An animal model of ascending UTIs and studies of bacterial isolates from different sites in patients with UTI provide evidence that phase variation can occur during *E. coli* UTI in vivo. Type 1 pilated *E. coli* organisms that were capable of phase variation were introduced into the mouse bladder in the pilated phase, and the bacteria recovered from the bladder and urine 24 or more hours after inoculation were tested for piliation. All of the animals had bladder colonization, and 78% of the bacteria recovered showed type 1 piliation. The bacteriologic state of the urine often differed from that of the bladder. The urine was sterile in 59% of the animals with bladder colonization, and the organisms recovered from the urine were often nonpilated.

When bladder and kidney cultures were examined 1, 3, and 5 days after intravesical inoculation of pilated bacteria, organisms recovered from the bladder remained pilated, whereas organisms recovered from the kidney showed significantly less piliation (Schaeffer et al, 1987) (Fig. 12-6).

Studies in humans using indirect immunofluorescence of fresh urine bacteria have confirmed in vivo expression and phase variation of pili. Analysis of the urine of adults with lower UTI detected type 1 pili in 31 of 41 specimens and P pili in 6 of 18 specimens (Kisielius et al, 1989). The piliation status of the bacterial population in the urine was heterogeneous, varying from predominantly pilated to a mixture of pilated and nonpilated cells (Fig. 12-7). Strains isolated from different sites in the urogenital tract showed variation in the state of piliation. These results demonstrate that type 1 and P pili are expressed and subject to phase variation in vivo during acute UTIs.

This process of phase variation has obvious biologic and clinical implications. For example, the presence of type 1 pili may be advantageous to the bacteria for initially adhering to and colonizing the bladder mucosa. Subsequently, type 1 pili may be unnecessary for strains in suspension in urine and in fact detrimental because they enhance apoptosis, phagocytosis, and killing by neutrophils

Figure 12-6. Time study after intravesical inoculation with *Escherichia coli* strain I-149 that compared the mean viable bacteria count (solid circles) and hemagglutination (HA) titer (open circles) for bladders (A), kidneys (B), and urine specimens (C) from the same animals. Each point is the mean of all the animals tested. The numbers in parentheses show the proportion of animals inoculated that gave positive cultures. The HA titers were tested after 18 hours of growth on agar. The HA titer of bacteria recovered from the kidney decreased significantly by day 5 ($P < 0.001$). (From Schaeffer AJ, Schwan WR, Hultgren SJ, et al. Relationship of type 1 pilus expression in *Escherichia coli* to ascending urinary tract infections in mice. *Infect Immun* 1987;55:373–80.)

Figure 12-7. Phase-contrast micrograph (A) and immunofluorescence micrograph (B) of a sample stained with antiserum to type 1 pili of strain I-49 and with fluorescein isothiocyanate-conjugated second antibody against nonadherent *Escherichia coli* in the urine of a patient with acute urinary tract infection show a mixture of piliated and nonpiliated (arrows in B) cells. (From Kisieli PV, Schwan WR, Amundsen SK, et al. In vivo expression and variation of *Escherichia coli* type 1 and P pili in the urine of adults with acute urinary tract infections. *Infect Immun* 1989;57:1656–62.)

(Silverblatt et al, 1979; Mulvey et al, 1998). In the kidney, P pili may then take over as the primary mediator of bacterial attachment via their binding to the glycolipid receptors (Stapleton et al, 1995).

Epithelial Cell Receptivity

Vaginal Cells

The significance of epithelial cell receptivity in the pathogenesis of ascending UTI has been studied initially by examining adherence of *E. coli* to vaginal epithelial cells and uroepithelial cells collected from voided urine specimens. Fowler and Stamey (1977) established that certain indigenous microorganisms (e.g., lactobacilli, *S. epidermidis*) avidly attached themselves to washed epithelial cells in large numbers. When vaginal epithelial cells were collected from patients susceptible to reinfection and compared with such cells obtained from controls resistant to UTI, the *E. coli* strains that cause cystitis adhered much more avidly to the epithelial cells from the susceptible women. These studies established increased adherence of pathogenic bacteria to vaginal epithelial cells as the first demonstrable biologic difference that could be shown in women susceptible to UTI.

Subsequently, Schaeffer and colleagues (1981) confirmed these vaginal differences in women, but in addition they observed that the increased bacterial adherence was also characteristic of buccal epithelial cells. As can be seen in Figure 12-8, there is a striking similarity in the ability of both cell types to bind to the same *E. coli* strain. In addition, there was a significant relationship between vaginal cell and buccal cell receptivity. Seventy-seven different *E. coli* strains were tested for their ability to bind to vaginal and buccal epithelial cells. A direct nonlinear relationship between buccal and vaginal adherence in controls and patients was confirmed for urinary, vaginal, and anal isolates. Thus high vaginal cell receptivity was associated with high buccal cell receptivity.

These observations emphasize that the increase in receptor sites for UPEC on epithelial cells from women with recurrent UTIs is not limited to the vagina and thus suggest that a genotypic trait for epithelial cell receptivity may be a major susceptibility factor in UTIs. This concept was extended by examining the human leukocyte antigens (HLAs), which are the major histocompatibility complex in humans and have been associated statistically with many diseases (Schaeffer et al, 1983). The A3 antigen was identified in 12 (34%) of the patients, which is significantly higher than the 8% frequency observed in healthy controls. Thus, HLA-A3 may be associated with increased risk of recurrent UTIs.

Figure 12-8. In vitro adherence of *Escherichia coli* to vaginal (A) and buccal (B) cells from healthy controls and patients with recurrent urinary tract infections. Values represent an average of 14 (A) and 11 (B) determinations in each individual. The open circles and bars represent the means + standard error of the mean. (From Schaeffer AJ, Jones JM, Dunn JK. Association of in vitro *Escherichia coli* adherence to vaginal and buccal epithelial cells with susceptibility of women to recurrent urinary tract infections. *N Engl J Med* 1981;304:1062–6.)

Variation in Receptivity. A small variation in both vaginal cell and buccal cell receptivity may be observed from day to day in healthy controls. Adherence ranges from 1 to 17 bacteria per cell and appears to be both cyclic and repetitive. When adherence was correlated with the days of a woman's menstrual cycle, higher values were noted in the early phase, diminishing shortly after the time of expected ovulation (day 14). The number of bacteria per epithelial cell often correlated with the value obtained on the same day of the menstrual cycle 1 or 2 months previously. Premenopausal women are particularly susceptible to attachment of uropathogenic *E. coli* and nonpathogenic lactobacilli at certain times during the menstrual cycle and to *E. coli* during the early stages of pregnancy. The importance of such hormones as estrogens in the pathogenesis of UTI is therefore a matter of great interest, especially because the clinical urologist may see women who have recurrent cystitis at regular intervals, possibly in response to these hormonal changes.

Reid and Sobel (1987) found that uropathogens attached in larger numbers to uroepithelial cells from women older than 65 years of age than to cells from premenopausal women 18 to 40 years of age. Raz and Stamm (1993) noted that susceptibility to recurrent UTI was increased by the lowered estrogen levels found in the postmenopausal women and that estrogen replacement decreased uropathogenic bacterial colonization and the incidence of UTI.

Blood group antigens and carbohydrate structures bound to membrane lipids or proteins also constitute an important part of the uroepithelial cell membrane. The presence or absence of blood group determinants on the surface of uroepithelial cells may influence an individual's susceptibility to a UTI. Sheinfeld and associates (1989) determined the blood group phenotypes in women with recurrent UTI and compared them with those of age-matched women controls. There is a higher frequency of Lewis

nonsecretor Le(a+b-) and recessive Le(a-b-) phenotypes among women with recurrent UTIs. There was no significant difference in the distribution of ABO or P blood group phenotypes. The Lewis antigen controls fucosylation. The protective effect in women with the secretor Le(a-b+) phenotype may be due to fucosylated structures at the vaginal cell surface or in the overlying mucus, which decreases availability of putative receptors for *E. coli* (Navas et al, 1993). The nonsecretor status has also been associated with female acute uncomplicated pyelonephritis, especially in premenopausal women (Ishitoya et al, 2002). Stapleton and coworkers (1995) have shown that unique *E. coli*-binding glycerides are found in vaginal epithelial cells from nonsecretors but not from secretors. These studies individually and collectively support the concept that there is an increased epithelial receptivity for *E. coli* on the introital, urethral, and buccal mucosa that is characteristic of women susceptible to recurrent UTIs and may be a genotypic trait.

The possibility that vaginal mucus might influence bacterial receptivity was investigated by Schaeffer and colleagues (1994). Type 1 piliated *E. coli* bound to all of the vaginal fluid specimens (Venegas et al, 1995). The binding capacity of vaginal fluid from women colonized with *E. coli* in vivo was greater than that from noncolonized women (Schaeffer et al, 1999). The importance of vaginal fluid in bacteria/epithelial cell interactions was investigated in an in vitro model that measured the effect of vaginal fluid on the binding of bacteria to an epithelial cell line (Gaffney et al, 1995). Vaginal fluid from colonized women enhanced binding of bacteria to epithelial cells. Conversely, vaginal fluid from noncolonized women inhibited adherence. Thus the vaginal fluid appears to influence adherence to cells and, presumably, vaginal mucosal colonization. Subsequent studies demonstrated that secretory IgA is the primary glycoprotein responsible for vaginal fluid receptivity (Rajan et al, 1999).

Bladder Cells

FimH binds mannosylated residues on the uroplakin molecules covering bladder superficial epithelial cells. The luminal surface of the bladder is lined by umbrella cells. The apical surfaces of umbrella cells appear as a quasi-crystalline array of hexagonal complexes composed of four integral membrane proteins known as *uroplakins* (Sun, 1996). In vitro binding assays have shown that two of the uroplakins, UPIa and UPIb, can specifically bind UPEC expressing type 1 pili (Wu et al, 1996). High-resolution freeze-fracture electron microscopy has shown that the tips of these pili, including the adhesins, are buried in the central cavity of the uroplakin hexameric rings (Mulvey et al, 2000) (Fig. 12-9A). Thus FimH-mediated binding to the bladder epithelium is the initial step in the intricate cascade of events leading to UTIs. Immediate urothelial responses to UPEC may be triggered by uroplakins themselves because FimH binding to UPIb was shown to result in phosphorylation of UPIII and subsequent UPIII-mediated increases in intracellular calcium (Thumbikat et al, 2009b).

UPEC Persistence in the Bladder. Soon after attachment to the epithelium, UPEC is quickly internalized into the bladder superficial cells (Martinez and Hultgren, 2002; Anderson et al, 2004b) (Fig. 12-9B). FimH is essential for UPEC invasion; isogenic FimH-mutants do not invade, and invasion of wild-type bacteria can be inhibited by the addition of mannose. In addition, polystyrene latex beads coated with FimH are quickly internalized in a process identical to bacteria expressing type 1 pili. This process is the result of localized actin rearrangement and engulfment of the

bound bacterium by zippering of the membrane around the microorganism (Martinez and Hultgren, 2002). Invasion into the superficial epithelium of the bladder allows UPEC to establish a new niche in an effort to protect itself from the host innate immune response (Anderson et al, 2004b).

Multiple urothelial receptors have been implicated in UPEC invasion. FimH was shown to bind integrins α_3 and β_1 in vitro, and anti-integrin antibodies blocked UPEC invasion of cultured urothelial cells, a process modulated by Src family kinases and integrin phosphorylation (Eto et al, 2007). FimH binding was also shown to result in phosphorylation of UPIII by casein kinase II (Thumbikat et al, 2009b). UPEC invasion was significantly reduced in cultured cells by targeted mutagenesis of the UPIII phosphorylation site, and perturbing casein kinase II function reduced UPEC invasion in vitro and in vivo. Thus UPEC invade urothelial cells by distinct receptors that, in turn, trigger diverse signaling cascades.

Once intracellular, the UPEC organisms rapidly grow and divide within the cell cytosol, forming small clusters of bacteria termed *early intracellular bacterial communities* (IBCs) (Anderson et al, 2004b; Justice et al, 2004). As they grow, the bacteria maintain their typical rod shape of approximately 3 μm and form a loosely organized cluster, with microorganisms randomly oriented in the cell cytoplasm. Between 6 to 8 hours after inoculation, early IBCs show a drop in bacterial growth rate resulting in doubling times greater than 60 minutes, a significant shortening of the bacterial morphology to an average of 0.7 μm , and a phenotypic switch into a biofilm-like community (Justice et al, 2004) (Fig. 12-9C). Similar bacteria-engorged urothelial cells have been identified in 22% of

Figure 12-9. Uropathogenic *Escherichia coli* (UPEC) binds, invades, and multiplies inside the superficial cells of the bladder epithelium. A, Scanning electron microscopy shows a single UPEC bound to the surface of a bladder cell. Type 1 pilus-mediated contact between bacterium and host cell initiates signaling cascades in the bladder cell, leading to localized actin rearrangements and membrane protrusions around the bacterium. Scale bar, 0.5 μm . B, Once inside the bladder superficial cells, UPEC rapidly multiplies to form disordered bacterial clusters in the host cell cytoplasm, called an early intracellular bacterial community (IBC). Bacteria are visible as dark-staining rods inside the cell in this hematoxylin and eosin (H&E)-stained thin bladder section. Scale bar, 100 μm . C, H&E-stained thin bladder section reveals a middle IBC, wherein the constituent bacteria have organized themselves into a biofilm-like state within the bladder cell. Scale bar, 20 μm . D, A late IBC, visible by H&E staining, is typified by detachment of peripheral bacteria and fluxing of these organisms into the bladder lumen. Scale bar, 10 μm . (From Anderson GG, Martin SM, Hultgren SJ. Host subversion by formation of intracellular bacterial communities in the urinary tract. *Microbes Infect* 2004;6:1094–101.)

voided urine specimens from patients with UTI with *E. coli* (Rosen et al, 2007). Importantly, UPEC isolated from the human IBC-like cells were capable of infecting mice and recapitulating IBCs (Garofalo et al, 2007).

Biofilms shield bacteria from environmental challenges such as antimicrobial agents and the host immune response (Donlan and Costerton, 2002). Characteristics of the biofilm that increase protection include the slower growth rate of the bacteria with associated physiologic changes, expression of factors that inhibit antimicrobial activity, and the inability of the antimicrobial agent to penetrate the biofilm matrix (Anderson et al, 2004b). The biofilm also protects the bacteria from neutrophils because they are unable to effectively penetrate the IBC and engulf the bacteria. In animal models, bacteria on the edge of IBCs eventually detach, differentiate to typical rod morphology, become motile, and then escape the host cell into the bladder lumen in a process called *fluxing* (Mulvey et al, 2001) (Fig. 12-9D). These bacteria may become highly filamentous, reaching up to 70 μm or greater in length. This process occurs by approximately 24 hours after inoculation (Justice et al, 2004). It is possible that the filaments may help the bacteria evade the immunologic response.

The escaped bacteria re-adhere and reinvade superficial cells to lead to second IBC formation. In subsequent rounds, further IBC formation occurs. After a few days, the invasive bacteria become more quiescent. In animal models, the bacteria can persist in this dormant reservoir state for some time before reemerging to cause recurrent UTIs (Anderson et al, 2004a). Indeed, in murine UTI, individuals with sterile urine nonetheless may contain thousands of viable UPEC within bladder tissue (Mulvey et al, 2001), suggesting that IBCs may be a transient intermediate in the establishment of stable UPEC reservoirs within the bladder. Exfoliation of superficial urothelial cells (see later) exposes underlying transitional cells. In contrast to the cytosolic UPEC aggregates characteristic of IBCs, UPEC invasion of transitional cells results in membrane-bound bacteria limited to two to four bacteria per cell (Justice et al, 2004). These intracellular UPEC remain quiescent, and thus such transitional cells are referred to as *quiescent intracellular reservoirs* (QIR) (Mysorekar and Hultgren, 2006). However, chemically perturbing the urothelium to evoke urothelial differentiation caused reemergence of UPEC from QIR marked by significant bacterial proliferation. Together, these findings suggest that bladder reservoirs of intracellular UPEC may contribute to recurrent UTI in susceptible individuals as the transitional cells undergo differentiation.

Natural Defenses of the Urinary Tract

Periurethral and Urethral Region

The normal flora of the vaginal introitus, the periurethral area, and the urethra usually contain microorganisms such as lactobacilli, coagulase-negative staphylococci, corynebacteria, and streptococci that form a barrier against uropathogenic colonization (Fair et al, 1970; Pfau and Sacks, 1977; Marrie et al, 1978). Changes in the vaginal environment related to estrogen, cervical IgA (Stamey et al, 1978), and low vaginal pH (Stamey and Timothy, 1975) may alter the ability of these bacteria to colonize. More commonly, however, acute changes in colonization have been associated with use of antimicrobial agents and spermicidal agents that alter the normal flora and increase the receptivity of the epithelium for uropathogens.

Little is known about the factors that predispose patients to urethral colonization with uropathogens. The proximity of the urethral meatus to the vulvar and perianal areas suggests that contamination occurs frequently. The nature of urethral defense mechanisms other than flow of urine is largely unknown. Bacterial multiplication in the normal urethra may be inhibited by the indigenous flora (Chan et al, 1984). Although colonization of the periurethral and urethral regions is prerequisite to most infections, the ability of the organisms to overcome the normal defense mechanisms of the urine and the bladder is clearly pivotal.

Urine

In general, fastidious organisms that normally colonize the urethra will not multiply in urine and rarely cause UTIs (Cattell et al, 1974). In contrast, urine will usually support the growth of nonfastidious bacteria (Asscher et al, 1968). Urine from normal individuals may be inhibitory, especially when the inoculum is small (Kaye, 1968). The most inhibitory factors are the osmolality, urea concentration, organic acid concentration, and pH. Bacterial growth is inhibited by either very dilute urine or a high osmolality when associated with a low pH. Much of the antimicrobial activity of urine is related to a high urea and organic acid content (Solomon et al, 1983). From a clinical perspective, however, these conditions do not appear to significantly distinguish between patients who are susceptible or resistant to infection.

Uromodulin (Tamm-Horsfall protein), a kidney-derived mannosylated protein that is present in an extraordinarily high concentration in the urine (>100 mg/mL), may play a defensive role by saturating all the mannose-binding sites of the type 1 pili, thus potentially blocking bacterial binding to the uroplakin receptors of the urothelium (Duncan, 1988; Kumar and Muchmore, 1990).

Recent studies have exploited next-generation DNA-sequencing technology to quantify any bacteria in normal urine and thus characterize the normal female urinary microbiome. Flora were identified in urine obtained by suprapubic aspiration from healthy participants that differed from voided urine and contained species that were uncultivable under either aerobic or anaerobic conditions (Wolfe et al, 2012). Aspirated urine (or urine obtained by catheter) that was culture-negative revealed diverse genera in a majority of participants. And while urine culture remains the gold standard for assessing UTI, this work also suggests a more complex bladder ecology: a single participant whose urine culture was positive for *E. coli* had relative DNA abundance of approximately 45% *Aerococcus*, 21% *Actinobaculum*, and only 2% *E. coli*. The authors then ask whether clinical symptoms reflect the low-abundance uropathogen, the more abundant fastidious bacteria, or both. Because most healthy participants exhibited urinary flora, future studies should define the role of the urinary microbiome in resistance and susceptibility to UTI.

Bladder

Bacteria presumably make their way into the bladder fairly often. Whether small inocula of bacteria persist, multiply, and infect the host depends in part on the ability of the bladder to empty (Cox and Hinman, 1961). Additional factors responsible for defense involve both innate and adaptive immunity and exfoliation of epithelial cells.

Immune Response

Pathogen Recognition. The host recognition of the pathogen is mediated by a series of pathogen-associated molecular pattern receptors (PAMPs), such as Toll-like receptors (TLRs) (Anderson et al, 2004b), which provide the link between recognition of invading organisms and development of the innate immune response. TLRs recognize molecular patterns that are conserved among many species of pathogens, such as lipopolysaccharide (LPS) and peptidoglycan (PG), and activate signaling pathways that initiate immune and inflammatory responses to kill pathogens. Superficial bladder epithelial cells express TLR4 on their membranes, which along with CD14 recognize LPS from the bacteria and activate the innate immune response (Anderson et al, 2004a). The newly identified TLR11, which recognizes UPEC and protects the kidneys from ascending infection, is also expressed on uroepithelial cells, as well as renal cells (Zhang et al, 2004).

The innate system response to an infection in the bladder or kidneys is primarily local inflammation.

The innate immune response occurs more rapidly than the adaptive response and involves a variety of cell types, including

polymorphonuclear leukocytes, neutrophils, macrophages, eosinophils, natural killer cells, mast cells, and dendritic cells. In addition, increased transcription of inducible nitric oxide synthase by polymorphonuclear leukocytes results in high levels of nitric oxide and related breakdown products that also have toxic effects on the bacteria (Poljakovic et al, 2001; Poljakovic and Persson, 2003). The innate response aids in establishing adaptive immunity because of interactions of macrophages, dendritic cells, and natural killer cells with T and B lymphocytes. Adaptive immunity involves the specific recognition of pathogens by T and B lymphocytes and production of high-affinity antibodies, a process that occurs 7 to 10 days after infection.

For additional data regarding the immunologic response to UTI, the idea of immunization, and the roles of lipopolysaccharide, see the Expert Consult website.

Multiple Roles for Lipopolysaccharide. Because TLR signaling triggers innate immune responses and mediates innate-adaptive interactions, diverse pathogens target TLR signaling. Consistent with this, TLR modulation has been identified in UPEC. UPEC was found to modulate urothelial inflammatory responses at the levels of nuclear factor- κ B (NF- κ B) activation and cytokine suppression, and this inflammatory suppression is widespread among clinical *E. coli* strains (Klumpp et al, 2001; Hunstad et al, 2005; Billips et al, 2007). In contrast to bacteria that modulate inflammatory responses through the action of secreted virulence factors, UPEC genetic screens identified genes associated with modification of TLR ligands (Hunstad et al, 2005; Billips et al, 2008). One such screen revealed that UPEC genes inhibiting urothelial cytokine responses were *walA*, *ampG*, and *alr*, genes encoding LPS O-antigen ligase, mureopeptide permease, and alanine racemase, respectively (Billips et al, 2008). *WalA* is involved in LPS biosynthesis, whereas both *ampG* and *alr* contribute to peptidoglycan metabolism, ligands for TLR4 and TLR2, respectively. UPEC strains with targeted deletions of *walA* or *ampG* were attenuated in a murine UTI model (Billips et al, 2008), indicating that modulation of TLR-mediated responses is important to UTI pathogenesis by UPEC. In a similar genetic screen, LPS biosynthesis operons *rfa* and *rfb* and the membrane protein isomerase *surA* were found to mediate cytokine suppression (Hunstad et al, 2005). Some UPEC strains even encode direct inhibitors of TLR signaling (Cirl et al, 2008). Together, these findings suggest that UPEC enhances virulence by modulating inflammatory responses at the level of TLR recognition, thereby extending a “window of opportunity” to establish infection by evading innate surveillance mechanisms.

Studies in murine UTI also suggest that these observations can be exploited for the development of novel vaccines against UPEC because immunizing with the *walA* mutant of UPEC strain NU14 conferred protection against challenge with wild-type NU14 (Billips et al, 2009). Immunization with the *walA* mutant of NU14, a phylogenetic group B2 strain, also conferred protection against other B2 strains, as well as A and D strains, and prevented kidney infection. Consistent with TLR-mediated skewing of immune responses (Schnare et al, 2001), *walA* mutant also promoted bladder sterilization of stable UPEC reservoirs, indicating enhanced cell-mediated immunity. These findings suggest that UPEC mutants represent live-attenuated vaccine candidates for recurrent UTI.

LPS has also emerged as a key determinant of the symptomatic response to *E. coli* in the urinary tract in recent studies using tactile allodynia as a measure of pelvic pain in murine UTI. The cystitis isolate NU14 evoked an acute pelvic pain response, whereas the asymptomatic bacteriuria *E. coli* strain 83972 did not, thus recapitulating the spectrum of human symptomatic response to bladder colonization (Rudick et al, 2010). Surprisingly, purified LPS preparations from NU14 and 83972 yielded the same pain/no pain responses as intact bacteria, yet the level of neutrophil influx and cytokines induced by each LPS was similar. Pain responses were also mediated by the LPS receptor TLR4. The O-antigen moiety that defines *E. coli* serotypes is an important determinant of the bacterial pain phenotype because, depending

upon O-antigen status, it was shown that a single *E. coli* strain could be shifted from an acute pain phenotype to a chronic pain phenotype, to a null pain phenotype (Rudick et al, 2012). Again, although pain responses were dependent upon TLR4, bacteria that elicited distinct pain responses induced similar pathology and neutrophil influx. These findings indicate that LPS defines the pain phenotype of *E. coli* and that bacterial pain is not correlated with inflammation. Moreover, because some strains lacking O antigen caused pain that persisted long after bacterial clearance, these findings demonstrate that *E. coli* can cause post-UTI chronic pain.

Induced Exfoliation. Mulvey and colleagues (1998) demonstrated that exfoliation and excretion of infected and damaged superficial cells is mediated by type 1 piliated bacteria that induce programmed cell death. By utilizing an in vivo mouse model, it has been demonstrated that mice exhibiting a strong exfoliation response to UPEC infiltration are unlikely to form IBCs (Anderson et al, 2004b). However, mice with a much milder exfoliation response tend to form biofilms, which become sequestered in the bladder and presumably could lead to recurrent UTIs. It has also been shown that many uropathogenic bacteria can suppress NF- κ B, increase apoptosis, and decrease the inflammatory responses (Klumpp et al, 2001), a process that could lead to subsequent bacterial invasion into deeper tissues. Thus in some instances apoptosis may be a bacterial offense maneuver rather than a host defense.

The same UPIII-casein kinase II signaling cascade mediating UPEC invasion also drives FimH-induced urothelial apoptosis (Thumbikat et al, 2009b). Consistent with this, increased UPIII expression during urothelial differentiation sensitizes urothelial cells to UPEC and FimH-induced apoptosis (Thumbikat et al, 2009a). However, because FimH-induced urothelial apoptosis and successful establishment of the UPEC intracellular life cycle are mutually exclusive, UPEC and/or host factors must define individual urothelial cell fates and thus the bifurcation between invasion and apoptosis.

Alterations in Host Defense Mechanisms

Obstruction

Obstruction to urine flow at all anatomic levels is a key factor in increasing host susceptibility to UTI. Obstruction inhibits the normal flow of urine, and the resulting stasis compromises bladder and renal defense mechanisms. Stasis also contributes to the growth of bacteria in the urine and their ability to adhere to the urothelial cells. In the animal model of experimental hematogenous pyelonephritis, the kidney is relatively resistant to infection unless a ureter is ligated. Under these circumstances, only the obstructed kidney becomes infected (Beeson and Guze, 1956). Clinical observations support the role of obstruction in pathogenesis of UTI and in increasing severity of infection. Mild episodes of cystitis or pyelonephritis can become life threatening when obstruction to urine flow becomes present. Although obstruction clearly increases the severity of infection, it need not be a predisposing factor. For example, men with large residual urine may remain uninfected for years. However, if they are catheterized, even small inocula may lead to severe infections that are difficult to eradicate.

Vesicoureteral Reflux

Hodson and Edwards (1960) first described the association of vesicoureteral reflux, UTI, and renal clubbing and scarring. Children with gross reflux and UTIs usually develop progressive renal damage manifested by renal scarring, proteinuria, and renal failure. Those with a lesser degree of reflux usually improve or completely recover spontaneously or after treatment of the UTI. In adults, the presence of reflux does not appear to decrease renal function unless there are stasis and concurrent UTIs.

The urinary tract is part of the secretory immune system. In pyelonephritis, IgG and SIgA appear in the urine and may become evident before antibodies are detected in the serum. These antibodies are synthesized locally within the kidney and may enhance bacterial opsonization and ingestion by local phagocytic cells. These antibodies may have further protective function. [Svanborg-Eden and Svennerholm \(1978\)](#) showed that IgG and SIgA derived from the urine of patients with acute pyelonephritis reduced in vitro adherence of the same strain of *E. coli* to uroepithelial cells. Similarly, immunization with *E. coli* P pili resulted in immunoglobulin production in experimental animals that prevented ascending pyelonephritis by reducing the adhesive capacity of the invading

autologous uropathogenic *E. coli* ([Roberts and Phillips, 1979](#); [O'Hanley et al, 1983](#)).

The possibility that immunologic factors may be modified to reduce susceptibility to infection has been explored primarily through immunization in animal and human systems. For example, in a monkey model, vaccination with P fimbria has been shown to reduce adherence of P-fimbriated *E. coli* to uroepithelial cells and prevent acute pyelonephritis ([Roberts and Phillips, 1979](#)). Similarly, vaccination of mice with FimH adhesin prevents cystitis in mice ([Langermann et al, 1997](#)). Vaccination of women may reduce colonization of the vaginal introitus and subsequent ascending bacteria ([Uehling et al, 1994](#)).

Underlying Disease

There is a high incidence of renal scarring in patients with underlying conditions that cause chronic interstitial nephritis, virtually all of which produce primary renal papillary damage. These conditions include diabetes mellitus, sickle cell disorders, adult nephrocalcinosis, hyperphosphatemia, hypokalemia, analgesic abuse, sulfonamide nephropathy, gout, heavy-metal poisoning, and aging (Freedman, 1979).

Diabetes Mellitus

An increased incidence of clinical asymptomatic and symptomatic UTIs appears to occur in women with diabetes mellitus, but there is no substantial increase among diabetic men (Vejlsgaard, 1973; Ooi et al, 1974; Forland et al, 1977; Meiland et al, 2002). Diabetes also results in three times more hospitalizations for acute pyelonephritis among women (10.86/10,000) than for men (3.32/10,000) (Nicolle et al, 1996). Autopsy studies have shown the incidence of pyelonephritis to be fourfold to fivefold higher in diabetic than in nondiabetic individuals (Robbins and Tucker, 1944). However, such studies may be misleading because it is difficult to distinguish renal parenchymal changes resulting from pyelonephritis from the interstitial inflammatory changes of diabetic nephropathy.

Although most UTIs in diabetic patients are asymptomatic, diabetes appears to predispose the patient to more severe infections. There is no evidence that increased frequency of infection is due to glycosuria (Geerlings et al, 2000). One study using antibody-coated bacteria techniques to localize the site of infection showed the upper urinary tract to be involved in nearly 80% of diabetic patients with UTIs (Forland et al, 1977). This evidence of increasing immunologic response in diabetic patients who acquire bacteriuria suggests renal parenchymal involvement and a potential increase in morbidity.

Infections are frequently caused by atypical organisms such as yeast and result in upper tract infections and significant sequelae such as emphysematous pyelonephritis, papillary necrosis, perinephric abscess, or metastatic infection (Wheat, 1980; Stapleton, 2002).

Renal Papillary Necrosis

The role of infection in the development and progression of renal papillary necrosis (RPN) is controversial. Multiple predisposing conditions have been associated with the development of RPN, particularly diabetes, analgesic abuse, sickle cell hemoglobinopathy, and obstruction (Box 12-2).

BOX 12-2 Conditions Associated with Renal Papillary Necrosis

Diabetes mellitus
 Pyelonephritis
 Urinary tract obstruction
 Analgesic abuse
 Sickle cell hemoglobinopathies
 Renal transplant rejection
 Cirrhosis of the liver
 Dehydration, hypoxia, and jaundice of infants
 Miscellaneous: renal vein thrombosis, cryoglobulinemia, renal candidiasis, contrast media injection, amyloidosis, calyceal arteritis, necrotizing angitis, rapidly progressive glomerulonephritis, hypotensive shock, acute pancreatitis

From Eknayan G, Qunibi WY, Grissom RT, et al. Renal papillary necrosis: an update. *Medicine* 1982;61:55.

Clinically, RPN is a spectrum of disease. Patients may have an acute fulminating illness with rapid progression or may have a chronic disease that is incidentally discovered. Some patients may chronically pass necrotic tissue in their urine (Hernandez et al, 1975), and some may never pass papillae (Lindvall, 1978). Retained necrotic papillae may calcify, especially in association with infection. Furthermore, this necrotic tissue may form the nidus for chronic infection. Opportunistic fungal infections have been reported (Madge and Lombardias, 1973; Juhasz et al, 1980; Vordermark et al, 1980; Tomashefski and Abramowsky, 1981). Renal sonography may be useful to diagnose RPN (Buonocore et al, 1980; Hoffman et al, 1982).

The early diagnosis of RPN is important to improve prognosis and reduce morbidity. In addition to chronic infection, patients with analgesic abuse-associated papillary necrosis may have an increased incidence of urothelial tumors; routine urinary cytologic examinations may be helpful to diagnose these tumors early (Jackson et al, 1978). In patients who have analgesic abuse-induced RPN, the disease stabilizes if the analgesic intake is stopped (Gower, 1976). Furthermore, adequate antimicrobial therapy to control infection and early recognition and treatment of ureteral obstruction caused by sloughed necrotic tissue can minimize a decline in renal function. A patient who suffers from an acute ureteral obstruction caused by a sloughed papilla and who has a concomitant UTI has a urologic emergency. In this case, immediate removal of the obstructing papilla by stone basket (Jameson and Heal, 1973) or acute drainage of the kidney by ureteral catheter or percutaneous nephrostomy is necessary.

Other conditions that may increase the susceptibility of the kidney to infection include hypertension and vascular obstruction (Freedman, 1979). The association of renal infection with several other renal diseases, including glomerulonephritis, atherosclerosis, and tubular necrosis, which are not associated with papillary necrosis, does not lead to pyelonephritis and scarring.

Human Immunodeficiency Virus

UTIs are fivefold more prevalent in HIV-positive individuals than in control subjects (Schonwald et al, 1999). Furthermore, the pathologic flora is typically more reminiscent of complicated UTIs. It also appears that HIV-positive patients with UTIs have a tendency for recurrence and require longer treatment.

Pregnancy

The prevalence of bacteriuria in pregnant women varies from 4% to 7%, and the incidence of acute clinical pyelonephritis ranges from 25% to 35% in untreated bacteriuric women (Stamey, 1980). This is probably the result of dilation of the ureters and pelvis of the kidney secondary to pregnancy-related hormonal alterations. In addition, urine obtained from pregnant women exhibits a more suitable pH for growth of *E. coli* in all stages of gestation (Asscher et al, 1973). It is not surprising that untreated bacteriuria in the first trimester is accompanied by a substantial increase in the incidence of acute pyelonephritis because half of these women have upper tract bacteriuria (Fairley et al, 1966).

For further details, see the Expert Consult website.

Spinal Cord Injury with High-Pressure Bladders

Of all patients with bacteriuria, no group compares in severity and morbidity with those who have spinal cord injury. Nearly all these patients require catheterization early after their injuries because of bladder overactivity or flaccidity, and significant numbers develop ureterectasis, hydronephrosis, reflux, and renal calculi. Bacteriologic and urodynamic advances in the management of these patients have vastly reduced their morbidity and mortality. Special problems associated with spinal cord injury are presented in a later section.

Untreated bacteriuria involving these dilated upper tracts could be expected to cause a significant number of abnormalities that should be radiologically apparent. [Kincaid-Smith and Bullen \(1965\)](#) performed a culture on 4000 women at their first antenatal visit. Of 240 bacteriuric women, 148 returned for excretory urography 6 weeks after delivery. Approximately 40% of these patients had radiologic abnormalities consistent with pyelonephritis or analgesic nephritis. [Brumfitt and colleagues \(1967\)](#) showed that the incidence of radiologic abnormalities in bacteriuria of pregnancy was

proportional to the difficulty in clearing the infection. Patients who responded promptly to a single course of therapy had a 23% incidence of radiologic abnormalities, but those who remained bacteriuric despite repeated therapeutic efforts had a 65% incidence of radiologic changes. Thus prolonged bacteriuria and pyelonephritis of pregnancy appear to be **associated** with significant radiologic abnormalities. However, there is little evidence to suggest that bacteriuria of pregnancy or acute pyelonephritis of pregnancy **causes** these renal radiologic abnormalities.

KEY POINTS: PATHOGENESIS

- Most UTIs are caused by bacteria, usually originating from the bowel flora.
- Bacterial virulence factors, including adhesin, play a role in determining which bacteria invade and the extent of infection.
- Increased epithelial cell receptivity predisposes patients to recurrent UTIs and is a genotypic trait.
- Obstruction to urine flow is a key factor in increasing host susceptibility to UTIs.

CLINICAL MANIFESTATIONS**Symptoms and Signs**

Cystitis is usually associated with dysuria, frequency, and/or urgency. Suprapubic pain and hematuria are less common. Lower tract symptoms are commonly present and usually predate the appearance of upper tract symptoms by several days. Pyelonephritis is classically associated with fever, chills, and flank pain. Nausea and vomiting may be present. Renal or perirenal abscess may cause indolent fever and flank mass and tenderness. In the elderly, the symptoms may be much more subtle (e.g., epigastric or abdominal discomfort) or the patient may be asymptomatic (Romano and Kaye, 1981). Patients with indwelling catheters often have asymptomatic bacteriuria, but fever associated with bacteremia may occur rapidly and become life threatening.

Diagnosis

Presumptive diagnosis of UTI is made by direct or indirect analysis of the urine and is confirmed by urine culture. The urine and the urinary tract are normally free of bacteria and inflammation. False-negative urinalysis and culture can occur in the presence of UTI, particularly early in an infection when the numbers of bacteria and WBCs are low or diluted by increased fluid intake and subsequent diuresis. Occasionally, the urine may be free of bacteria and WBCs despite bacterial colonization and inflammation of the uroepithelium (Elliott et al, 1985; Hultgren et al, 1985). False-positive urinalysis and culture are caused by contamination of the urine specimen with bacteria and WBCs during collection. This is most likely to occur in voided specimens but can also occur during urethral catheterization. Suprapubic aspiration of bladder urine is least likely to cause contamination of the specimen; therefore it provides the most accurate assessment of the status of bladder urine.

Urine Collection

Voided and Catheterized Specimens. Diagnostic accuracy can be improved by reducing bacterial contamination when the urine is collected. In circumcised men, voided specimens require no preparation. For men who are not circumcised, the foreskin should be retracted and the glans penis washed with soap and then rinsed with water before specimen collection. The first 10 mL of urine (representative of the urethra) and a midstream specimen (representative of the bladder) should be obtained. Prostatic fluid is obtained by performing digital prostatic massage and collecting the expressed prostatic fluid on a glass slide. In addition, collection of the first 10 mL of voided urine after massage will reflect the prostatic fluid added to the urethral specimen. Catheterization of a male patient for urine culture is not indicated unless the patient cannot urinate.

In women, contamination of a midstream urine specimen with introital bacteria and WBCs is common, particularly when the woman has difficulty spreading and maintaining separation of the labia. Therefore the female should be instructed to spread the labia, wash and cleanse the periurethral area with moist gauze, and then collect a midstream urine specimen. Cleansing with antiseptics is

not recommended because they may contaminate the voided specimen and provide a false-negative urine culture. The voided specimen is contaminated if it shows evidence of vaginal epithelial cells and lactobacilli on urinalysis, and a midcatheterized specimen should be collected.

Catheterization and collection of a midcatheterized specimen is more accurate than a voided specimen, but carries a risk of iatrogenic infection. Although a single dose of an oral antimicrobial agent such as trimethoprim-sulfamethoxazole (TMP-SMX) may be effective for prophylaxis because antimicrobial usage encourages development of bacterial resistance, prophylaxis should be limited to high-risk patients.

Suprapubic Aspiration. Suprapubic aspiration is highly accurate, but because it carries some morbidity there is limited clinical usefulness except for a patient who cannot urinate on command, such as patients with spinal cord injuries. It is highly useful in newborns (Newman et al, 1967) and in patients with paraplegia. A single aspirated specimen reveals the bacteriologic status of the bladder urine without introducing urethral bacteria, which can start a new infection.

Before a suprapubic aspiration is performed, the patient should force fluids until the bladder is full. The site of the needle puncture is in the midline, between the symphysis pubis and the umbilicus and directly over the palpable bladder. The full bladder in the male is usually palpable because of its greater muscle tone; unfortunately, the full bladder in the female is frequently not palpable. In such patients, the physician performing the aspiration must rely on the observation that suprapubic pressure directly over the bladder produces an unmistakable desire to urinate. After determining the approximate site for needle puncture, the local area is shaved and the skin is cleansed with an alcohol sponge; a cutaneous wheal is raised with a 25-gauge needle and any local anesthetic. A 3.5-inch spinal, 22-gauge needle is introduced through the anesthetized skin. The progress of the needle is arrested just below the skin within the anesthetized area, and with a quick plunging action, similar to that of any intramuscular injection, the needle is advanced into the bladder. Most patients experience more discomfort from the initial anesthetization of the skin than during the second stage when the needle is advanced into the bladder. After the needle has been introduced, a 20-mL syringe is used to aspirate 5 mL of urine for culture and 15 mL of urine for centrifugation and urinalysis. The obturator is reintroduced into the needle, and both needle and obturator are withdrawn. A small dressing is placed over the needle site in the skin. If urine is not obtained with complete introduction of the needle, the patient's bladder is not full and is usually deep within the retropubic area. When no urine is obtained on the first attempt, it is probably wise to wait until the bladder is full.

Urinalysis

For patients with urinary symptoms, microscopic urinalysis for bacteriuria, pyuria, and hematuria should be performed. Urinalysis provides rapid identification of bacteria and WBCs and presumptive diagnosis of UTI. Usually, the sediment from an approximately 5- to 10-mL specimen obtained by centrifugation for 5 minutes at 2000 rpm is analyzed. Microscopic bacteriuria is found in more than 90% of infections with counts of 10^5 colony-forming units (cfu) per milliliter of urine or greater and is a highly specific finding (Stamm, 1982; Jenkins et al, 1986). However, bacteria are usually not detectable microscopically with lower colony count infections (10^2 to 10^4 /mL). This important error (i.e., a false-negative result) occurs because of the limitation imposed by the microscope on the volume of urine that can be observed. If the volume of urine that can easily rest beneath a standard 22-mm cover glass is carefully measured (0.01 mL) and the number of high dry fields ($\times 570$ magnification) present beneath the cover glass is estimated, it is disturbing to find that one high dry field represents a volume of approximately 1/30,000 mL. There are excellent studies showing that the bacterial count must be approximately 30,000/mL before bacteria can be found in the sediment, stained or unstained, spun or unspun (Sanford et al, 1956; Kunin, 1961). For these

reasons, a negative urinalysis for bacteria never excludes the presence of bacteria in numbers of 30,000/mL and less.

The second error of urinalysis (i.e., a false-positive result) is the reverse of the first error: bacteria are seen in the microscopic sediment, but the urine culture shows no growth. The voided urine from a female patient can contain many thousands of lactobacilli and corynebacteria. These bacteria are readily seen under the microscope; and although they are gram-positive, they often appear gram-negative (gram-variable) if stained. Strict anaerobes, usually gram-negative bacilli, also make up a significant mass of the normal vaginal flora (Marrie et al, 1978).

In practice, these problems can be minimized by using other information provided by urinalysis that can help the clinician to decide whether a patient has a UTI such as pyuria (Stamm et al, 1982b). The validation of the midstream urine specimen can be questioned if numerous squamous epithelial cells (indicative of preputial, vaginal, or urethral contaminants) are present.

Pyuria and hematuria are good indicators of an inflammatory response. Although the number of WBCs per high-power field in a centrifuged urine sample is useful, it is important to remember that other factors can influence the number of cells seen. These include the state of hydration; the intensity of tissue reaction; the method of urine collection; the volume, speed, and time of centrifugation; and the volume in which the sediment is resuspended.

The presence of bacteriuria has a sensitivity for UTI of 40% to 70%, and a specificity of 85% to 95%, depending on the number of bacteria observed (Fihn, 2003).

Significant pyuria can be determined simply and reliably with a microscope by accurately examining the centrifuged sediment or by using a hemocytometer to count the number of WBCs in the unspun urine. One to 2 WBCs per high-power field (HPF) in sediment from a centrifuged specimen represents about 10 WBCs/mm³ in an unspun specimen. More than 2 WBCs per HPF in a centrifuged specimen or 10 WBCs/mm³ of urine correlates well with the presence of bacteriuria and is rarely seen in nonbacteriuric patients (Stamm et al, 1981). In clinical studies, determination of pyuria in voided urine specimens has a reported sensitivity of 80% to 95% and a specificity of 50% to 76% for UTI (depending on the definition of infection, the patient population, and the method used to evaluate for pyuria) (Stamm, 1982; Schultz et al, 1984; Wong et al, 1984; Wigton et al, 1985).

The absence of pyuria should cause the diagnosis of UTI to be questioned until urine culture data are available. Conversely, many diseases of the urinary tract produce significant pyuria in the absence of bacteriuria. Whereas tuberculosis is the well-recognized example of abacterial pyuria, staghorn calculi and stones of smaller size can produce intense pyuria with clumps of WBCs in the absence of UTI. Almost any injury to the urinary tract, from chlamydial urethritis to glomerulonephritis and interstitial cystitis, can elicit large numbers of fresh polymorphonuclear leukocytes (glitter cells). Depending on the stage of hydration, the intensity of the tissue reaction producing the cells, and the method of urine collection, any number of WBCs can be seen in the microscopic sediment in the presence of an uninfected urinary tract.

Microscopic hematuria is found in 40% to 60% of cases of cystitis and is uncommon in other dysuric syndromes (Stamm et al, 1980b; Wigton et al, 1985).

Rapid Screen Methods. Biochemical and enzymatic tests have been devised to detect bacteriuria and pyuria (Pezzlo, 1988). The Griess test detects the presence of nitrite in urine that is formed when bacteria reduce the nitrate normally present in urine. Tests for detecting pyuria by determining leukocyte esterase activity have also been developed (Chernow et al, 1984). In a study comparing traditional urine culture with these indirect tests, the combination of nitrite and leukocyte esterase tests (either test positive) had a sensitivity of 71% and a specificity of 83% when compared with 10³ cfu/mL or greater of urine cultures (Pfaller and Koontz, 1985). However, several investigators (Pels et al, 1989; Hurlbut and Litenberg, 1991) noted substantial variability in the sensitivity and specificity results, which could be markedly influenced by the types of patients and infections chosen to evaluate the tests. This concept

of spectrum bias was illustrated by a study that reported differences in the sensitivity of reagent strip testing, ranging from 56% to 92%, by changing only the groups of patients included in the analysis. Although false-positive results are relatively uncommon, the borderline sensitivity of these tests, especially among patients with less characteristic symptoms of UTIs, does not allow these inexpensive tests to replace careful microscopic urinalysis in symptomatic patients (Semeniuk and Church, 1999). Their main role is in screening asymptomatic patients (Pezzlo, 1988).

Urine Culture

Two techniques for urine culture are available. Direct surface plating of a known amount of urine on split-agar disposable plates is the traditional quantitative culture technique used by most microbiology laboratories. One half of the plate is blood agar, which grows both gram-positive and gram-negative bacteria, and the other is desoxycholate or eosin-methylene blue (EMB), which grows gram-negative bacteria (some of them, such as *E. coli*, in a very characteristic manner). Simple curved-tip eye droppers are sufficient to deliver about 0.1 mL of urine onto each half of the plate. After overnight incubation, the number of colonies is estimated, often identified (after some experience), and multiplied by 10 to report the number of cfu per milliliter of urine. The technique has been presented elsewhere in detail (Stamey, 1980).

A simpler but somewhat less accurate technique is the use of dip slides (Fig. 12-10). These inexpensive plastic slides are attached to screw-top caps; they have soy agar (a general nutrient agar to grow all bacteria) on one side and EMB or MacConkey agar for gram-negative bacteria on the opposite side. A slide is dipped into urine, the excess is allowed to drain off, and the slide is replaced in its plastic bottle and incubated. The volume of urine that attaches to the slide is between 1/100 mL and 1/200 mL. Hence, the colony count is 100 to 200 times the number of colonies that become visible with incubation. In actual practice, the growth is compared with a visual standard and reported as such. The species of bacteria is more difficult to recognize when this technique is used, but the technique is completely adequate.

The urine must be refrigerated immediately on collection and should be cultured within 24 hours of refrigeration. One advantage to the dip slide is the ease with which the urine can be immediately cultured without the necessity of refrigeration. Patients can culture their own urine at home, keep the slide at room temperature, and bring it to the office within 48 hours.

Although most bacteria allowed to incubate for several hours in bladder urine reach cfu counts of 10⁵/mL, this statistical

Figure 12-10. The dip slide on the left is compared with a split-agar surface plate on the right. The urine contained 10,000 colonies of *Klebsiella* per milliliter (about 200 times the number of colonies on the dip slide and 10 times the number on either side of the split-agar plate).

number is fraught with two limitations. The first is that 20% to 40% of women with symptomatic UTIs present with bacteria counts of 10^2 to 10^4 cfu/mL of urine (Stamey et al, 1965; Mabeck, 1969; Kunz et al, 1975; Kraft and Stamey, 1977), probably because of the slow doubling time of bacteria in urine (every 30 to 45 minutes) combined with frequent bladder emptying (every 15 to 30 minutes) from irritation. Thus, in dysuric patients, an appropriate threshold value for defining significant bacteriuria is 10^2 cfu/mL of a known pathogen (Stamm and Hooton, 1993). Fortunately, most of these patients have symptoms of UTI and pyuria on urinalysis.

The second limitation of the 10^5 cutoff is overdiagnosis. Women susceptible to infection often carry large numbers of pathogenic bacteria on the perineum that contaminate otherwise sterile bladder urine. Uncircumcised men may harbor uropathogenic bacteria on their foreskins. In the original studies by Kass (1960), a single culture of 10^5 cfu/mL or more had a 20% chance of representing contamination. There is no statistical way to avoid these two major limitations on the interpretation of the midstream voided culture in women and in uncircumcised men without careful preparation.

Localization

Kidney

Fever and Flank Pain. Fever and flank pain are thought to indicate pyelonephritis, but few studies have tested the hypothesis. Aggressive localization studies in children and adults (Huland and Busch, 1982; Busch and Huland, 1984), as well as in patients with end-stage renal disease (Huland et al, 1983), have shown substantial incidences of fever and even flank pain in bacteriuric patients in whom infection was localized to the bladder (see the later section on Acute Pyelonephritis).

Ureteral Catheterization. Ureteral catheterization allows not only separation of bacterial persistence into upper and lower urinary tracts but also separation of the infection between one kidney and the other, and even localization of infection to ectopic ureters or to nonrefluxing ureteral stumps (by using saline solution irrigation) (Stamey, 1980).

Stamey began in 1959 to localize the site of bacteriuria by ureteral catheterization studies; the technique was published in 1963 (Stamey and Pfau, 1963) and the results in 1965 (Stamey et al, 1965). The technique is simple but exacting; the urologist should consult a more detailed description (Stamey, 1980) before actually performing this localization technique. The validity depends on controlling the number of bacteria from the bladder that contaminate the ureteral catheters as they pass through the bladder into the ureteral orifices. The bladder must be thoroughly irrigated before both ureteral catheters are passed into a small volume of residual irrigating fluid. A sample is obtained through both ureteral catheters simultaneously, and then each catheter is passed into the ureter or renal pelvis. Four serial cultures are obtained from each kidney. It is mandatory that the patient be started on the appropriate antimicrobial agent before leaving the cystoscopy room. In addition to quantitative bacterial counts on each specimen, determination of either specific gravity or urine creatinine levels on the renal samples can be very helpful in interpreting a change in diuresis in relation to bacterial counts. Examples of infections localized to the bladder, to one kidney, and to both kidneys have been published (Stamey, 1980). Clinical examples of results from each site are shown in Table 12-1 on the Expert Consult website.

When this technique was applied to large numbers of bacteriuric patients, 45% were found to have bladder infection only; 27%, unilateral renal bacteriuria; and 28%, bilateral renal bacteriuria (Table 12-2 on the Expert Consult website) (Stamey et al, 1965). These figures have been confirmed by at least five investigators in three countries (the United States, England, and Australia) and can be taken as a good approximation for any general bacteriuric adult population. Although renal stones and other kidney abnormalities in the presence of bacteriuria can increase the proportion of

renal infections, the urologist should never assume the kidney is involved if an important decision is to be made.

Tissue and Stone Cultures. It is clinically useful to culture stones removed from the urinary tract to document that bacteria reside within their interstices. Tissue cultures are primarily useful for research information.

Using sterile technique at the operating table, the surgeon places the stone or fragment of tissue into a sterile culture tube containing 5 mL of saline solution; the culture is packed in ice and sent to the bacteriologic laboratory, where, after agitation of the stone or tissue in the 5 mL of saline solution, 0.1 mL is surface-streaked on both blood agar and EMB agar. The saline solution is then poured off the specimen, and, with sterile forceps, the stone or tissue is transferred to a second 5 mL of sterile saline solution. After agitation to ensure a reasonable washing action, the saline solution is again decanted and the specimen is transferred to a third 5 mL of saline solution and finally to a fourth 5 mL of saline solution. This last saline solution wash is cultured quantitatively in the same manner as the first. The remainder of this fourth 5 mL of saline solution is poured with the stone into a sterile mortar and pestle dish.

After the stone is crushed (or the tissue is ground in a tissue blender) in the fourth saline solution wash, 0.1 mL is again cultured on both blood agar and EMB agar. The difference in colony counts between the first and the fourth saline solution washes represents the washing effect of the saline solution transfers on the surface bacteria of the stone or tissue. The difference between the fourth saline wash before and after crushing (or grinding, for tissue) represents the difference between surface bacteria and bacteria within the specimen.

Prostate and Urethral Localization Studies. The technique for localizing infections to the urethra or prostate is covered in detail in Chapter 13.

KEY POINTS: CLINICAL MANIFESTATIONS

- The urine and the urinary tract are normally sterile.
- Bacteriuria and WBCs provide a presumptive diagnosis of UTI.
- In diagnosing patients, 10^2 cfu/mL confirms a symptomatic UTI.

IMAGING TECHNIQUES

Imaging studies are not required in most cases of UTI because clinical and laboratory findings alone are sufficient for correct diagnosis and adequate management of most patients. However, infection in most men or a compromised host, febrile infections, signs or symptoms of urinary tract obstruction, failure to respond to appropriate therapy, and a pattern of recurrent infections suggesting bacterial persistence within the urinary tract warrant imaging for identification of underlying abnormalities that require modification of medical management or percutaneous or surgical intervention.

Indications

Radiologic studies are unnecessary for evaluation of most women with genitourinary infections. Several reports of women patients with recurrent UTIs show that excretory urograms are unnecessary for routine evaluation if women who have special risk factors are excluded (Fair et al, 1979; Engel et al, 1980; Fowler and Pulaski, 1981; Fairchild et al, 1982). In none of these studies did excretory urograms yield information that was useful in the management of these patients. Furthermore, excluding excretory urograms in the routine evaluation of such patients represents a substantial financial saving.

However, in high-risk patients, including women with febrile infections and most men, radiologic studies may determine acute

TABLE 12-1 Clinical Examples of Ureteral Catheterization Studies in Localizing the Site of Bacteriuria

SOURCE OF RENAL INFECTION	BLADDER INFECTION (BACTERIA/mL)	LEFT RENAL INFECTION (BACTERIA/mL)	RIGHT RENAL INFECTION (BACTERIA/mL)	BILATERAL (BACTERIA/mL)

BOX 12-3 Indications for Radiologic Investigation in Acute Clinical Pyelonephritis

Potential ureteral obstruction (e.g., caused by stone, ureteral stricture, tumor)
 History of calculi, especially infection (struvite) stones
 Potential papillary necrosis (e.g., patients with sickle cell anemia, severe diabetes mellitus, analgesic abuse)
 History of genitourinary surgery that predisposes to obstruction, such as ureteral reimplantation or ureteral diversion
 Poor response to appropriate antimicrobial agents after 5 to 6 days of treatment
 Diabetes mellitus
 Polycystic kidneys in patients in dialysis or with severe renal insufficiency
 Neuropathic bladder
 Unusual infecting organisms, such as tuberculosis, fungus, or urea-splitting organisms (e.g., *Proteus*)

infectious processes that require further intervention or may find the cause of complicated infections.

First, radiologic procedures are needed in patients with risk factors that may require intervention in addition to antimicrobial treatment (Box 12-3).

A UTI associated with possible urinary tract obstruction must be evaluated. These are patients with calculi, especially infection (struvite) stones; ureteral tumors; ureteral strictures; congenital obstructions; or previous genitourinary surgery, such as ureteral reimplantation or urinary diversion procedures that may have caused obstruction. Patients with diabetes mellitus can develop special complications from UTIs; they may acquire emphysematous pyelonephritis or papillary necrosis. Impacted necrotic papillae may cause acute ureteral obstruction. Patients with polycystic kidney disease who are on dialysis are particularly prone to developing perinephric abscesses.

Urologic imaging is indicated in patients whose symptoms of acute clinical pyelonephritis persist after 5 to 6 days of appropriate antimicrobial therapy; they often have perinephric or renal abscesses. In addition, patients with unusual organisms, including urea-splitting organisms (e.g., *Proteus* species), should be examined for abnormalities within the urinary tract, such as obstructing stones, strictures, or fungus balls.

The second reason for radiologic evaluation is to diagnose a focus of bacterial persistence. In patients whose bacteriuria fails to resolve after appropriate antimicrobial therapy or who have rapid recurrence of infection, abnormalities that cause bacterial persistence should be sought. Although these patients are uncommon, it is important to identify them because they may have correctable urologic abnormalities that represent the only surgically curable causes of recurrent UTIs. Acquired or congenital urologic abnormalities that can cause unresolved or recurrent UTIs are listed in Box 12-4.

Ultrasonography

The renal ultrasound study is an important renal imaging technique because it is noninvasive, easy to perform, and rapid and offers no radiation or contrast agent risk to the patient. It is particularly useful in identifying calculi and hydronephrosis, pyonephrosis, and perirenal abscesses. A single radiograph for calculi should accompany ultrasonography. Ultrasonography is also useful for diagnosing postvoid residual urine. A disadvantage is that the study is dependent on the interpretative and performance skills of the examiner. Furthermore, the study may be technically poor in patients who are obese or who have dressings, drainage tubes, or open wounds overlying the area of interest.

BOX 12-4 Correctable Urologic Abnormalities That Cause Bacterial Persistence

Infection stones
 Chronic bacterial prostatitis
 Unilateral infected atrophic kidneys
 Ureteral duplication and ectopic ureters
 Foreign bodies
 Urethral diverticula and infected periurethral glands
 Unilateral medullary sponge kidneys
 Nonrefluxing, normal-appearing, infected ureteral stumps after nephrectomy
 Infected urachal cysts
 Infected communicating cysts of the renal calyces
 Papillary necrosis
 Perivesical abscess with fistula to bladder

Computed Tomography and Magnetic Resonance Imaging

The radiologic modalities that offer the best anatomic detail are CT and MRI. They are more sensitive than excretory urography or ultrasonography in the diagnosis of acute focal bacterial nephritis, renal and perirenal abscesses, and radiolucent calculi (Kuhn and Berger, 1981; Mauro et al, 1982; Wadsworth et al, 1982; Soulen et al, 1989; Soler et al, 1997). When used to localize renal and perirenal abscesses, CT improves the approach to surgical drainage and permits percutaneous approaches. MRI has not superseded CT in the evaluation of renal inflammation, but it has provided some advantages in delineating extrarenal extension of inflammation.

Voiding Cystourethrogram

The voiding cystourethrogram is an important examination in assessing vesicoureteral reflux. It may be used to evaluate patients with neuropathic bladders and the rare female patient who has a urethral diverticulum causing her persistent infections.

Radionuclide Studies

Hippuran I-131 and technetium-99m (^{99m}Tc) glucoheptonate scans are used to detect focal parenchymal damage, renal function impairment, and decreased renal perfusion in acute renal infections (McAfee, 1979). Although gallium-67 scanning has been reported to be useful in the diagnosis of pyelonephritis and renal abscess, it is uncommonly required and may be positive in noninfectious entities. Indium-111-labeled WBC studies have limited efficacy in establishing the presence of an inflammatory focus, particularly when the patient's clinical presentation does not suggest an infectious process.

KEY POINTS: IMAGING TECHNIQUES

- Imaging studies are not required in most women with UTIs.
- Men and compromised patients or those who do not respond to therapy require imaging to identify abnormalities.
- CT and MRI provide the best anatomic data on the site, cause, and extent of infection.

PRINCIPLES OF ANTIMICROBIAL THERAPY

Therapy for UTIs must ultimately eliminate bacterial growth in the urinary tract. This can occur within hours if the proper antimicrobial agent is used (Stamey, 1980). Efficacy of the antimicrobial therapy is critically dependent on the antimicrobial levels in the

TABLE 12-3 Serum and Urinary Antimicrobial Levels in Adults*

ANTIMICROBIAL AGENT	DOSE (mg)	PEAK SERUM LEVEL (mg/L)	PERCENTAGE BOUND TO PROTEIN	HALF-LIFE SERUM PEAK (hr)	MEAN (ACTIVE) URINE LEVELS* (g/mL)	DOSE EXCRETED IN URINE (%)	DOSE ACTIVE IN URINE (IF DIFFERENT) (%)

*These average urinary concentrations are based on the amount of biologically active drug excreted by normal kidneys at a urine flow rate of 1200 mL/24 hr.

Modified from Stamey TA. The pathogenesis and treatment of urinary infections. Baltimore: Williams & Wilkins; 1980. p. 59.

urine and the duration that this level remains above the minimal inhibitory concentration of the infecting organism (Hooton and Stamm, 1991). Hence, resolution of infection is closely associated with the susceptibility of the bacteria to the concentration of the antimicrobial agent achieved in the urine (McCabe and Jackson, 1965; Stamey et al, 1965, 1974). The concentration of useful antimicrobial agents in the serum and urine of healthy adults is shown in Table 12-3, which demonstrates that the urinary levels are often several hundred times greater than the serum levels. Inhibitory concentrations in urine are achieved after oral administration of all commonly used antimicrobial agents, except for the macrolides (erythromycin). The question of serum levels versus urinary levels is a practical one because the policy of testing antimicrobial susceptibility agents at concentrations obtainable only in the serum discourages the physician from using drugs that are effective at the urinary level; for example, oral penicillin G for *E. coli* and *Proteus mirabilis* and tetracycline for *P. aeruginosa*.

The concentration of the antimicrobial agent achieved in blood is not important in treatment of uncomplicated UTIs. However, blood levels are critical in patients with bacteremia and febrile urinary infections consistent with parenchymal involvement of the kidney and prostate.

In patients with renal insufficiency, dosage modifications are necessary for agents that are cleared primarily by the kidneys and cannot be cleared by another mechanism. In renal failure, the kidneys may not be able to concentrate an antimicrobial agent in the urine; hence, difficulty in eradicating bacteria may occur. Urinary tract obstruction may also reduce concentration of antimicrobial agents within the urine.

A decision regarding the antimicrobial selection and the duration of therapy must consider the spectrum of activity of the drug against the known pathogen or the most probable pathogen based on the presumed source of acquisition of infection, whether the infection is judged to be uncomplicated or

complicated, potential adverse effects, and cost. An often under-emphasized but important characteristic is the drug's impact on the bowel and vaginal flora and the hospital bacterial environment. Bacterial susceptibility will vary dramatically in patients exposed to antimicrobial agents and in individuals in inpatient and outpatient settings. It is imperative that each clinician keep abreast of changes that affect antimicrobial use and susceptibility patterns.

Bacterial Resistance

In the past several years, the frequency and spectrum of antimicrobial-resistant UTIs have increased in both the hospital and community. The increasing frequency of drug resistance has been attributed to combinations of microbial characteristics, bacterial selection pressure caused by antimicrobial use, and societal and technologic changes that enhance the transmission of drug resistance (Shepherd and Pottinger, 2013). Resistance patterns have been shown to vary by geographical location (Manges et al, 2001).

Bacterial resistance may occur because of inherited chromosomal-mediated resistance or by acquired chromosomal- or extrachromosomal (plasmid)-mediated resistance caused by exposure of an organism to antimicrobial agents.

Inherited chromosomal resistance exists in a bacterial species because of the absence of the proper mechanism on which the antimicrobial agent can act. For example, *Proteus* and *Pseudomonas* species are always resistant to nitrofurantoin.

Acquired chromosomal resistance occurs during therapy for UTIs. Before antimicrobial therapy, relatively resistant bacteria called *mutators* may be present in the urine at very low concentrations. Frequencies in mutations for high-level antimicrobial resistance are 1000-fold higher in mutators than in normal strains, indicating the increased adaptability of these strains (Miller et al, 2004). The remainder of the bacteria, which are susceptible to the administered

antimicrobial agent, will be eradicated by therapy, but within 24 to 48 hours a repeat urine culture will show high bacterial counts of the resistant mutant. In essence, the antimicrobial therapy has selected out the resistant mutant. This phenomenon is most likely to occur when the antimicrobial level in the urine is close to or below the minimal inhibitory concentration of the drug. **Selection of resistant clones in the course of therapy for a previously sensitive bacteriuric population occurs between 5% and 10% of the time, clearly not an insignificant factor and one that must be considered in resolving bacteriuria.** Underdosing and noncompliance, as well as diuresis induced by increased fluid intake, can contribute to this process. Therefore the clinician should select an antimicrobial agent with a urinary concentration that exceeds the minimal inhibitory concentration by the widest margin possible, avoid underdosing, and emphasize patient compliance.

Extrachromosomal-mediated resistance may be acquired and transferable via plasmids, which contain the genetic material for the resistance. This so-called R-factor resistance occurs in the bowel flora and is much more common than selection of preexisting mutants in the urinary tract. All antimicrobial classes are capable of causing plasmid-mediated resistance. However, for the fluoroquinolones, resistance is rarely transmitted by plasmids, and nitrofurantoin plasmid-mediated resistance has not been reported. Therefore patients previously exposed to β -lactams, aminoglycosides, sulfonamides, TMP, and tetracycline will often have R-factor resistance to both the antimicrobial agent to which the bacteria were exposed and also to other antimicrobial agents. In addition, the plasmids carrying the resistant genetic material are transferable both within species and across genera. Thus, for example, a patient receiving tetracycline may harbor several bowel strains that are resistant to tetracycline, ampicillin, sulfonamides, and TMP. **Because the bowel flora is the major reservoir for bacteria that ultimately colonize the urinary tract, infections that occur after antimicrobial therapy and that can cause plasmid-mediated resistance are commonly caused by organisms with multidrug resistance.** However, resistant *E. coli* in the bowel flora that infect the urinary tract almost always show susceptibility to nitrofurantoin or to the quinolones.

Antimicrobial resistance is also influenced by the duration and amount of antimicrobial agent used. For example, documented increased use of fluoroquinolones in the hospital setting has been directly associated with increased resistance of bacteria (particularly *Pseudomonas*) to the fluoroquinolones. Resistance tends to increase the longer the agent is used. Conversely, reduction in duration of therapy and in the amount of the drug used may lead to reemergence of more susceptible strains.

Most studies reporting antimicrobial resistance have been based on surveys of laboratory isolates, generally without correlation with clinical or epidemiologic factors (e.g., the presence and nature of symptoms, age, sex, and whether the infection was complicated). Gupta and colleagues (2011) determined the prevalence of and trends in antimicrobial resistance among uropathogens isolated from a large, well-defined population of women with acute uncomplicated cystitis. The prevalence of resistance to TMP-SMX and ampicillin is greater than 20% in many countries worldwide (Gupta et al, 2011) and resistance to cephalothin has increased significantly, whereas resistance to nitrofurantoin and ciprofloxacin has remained uncommon. **However, fluoroquinolone resistance of *E. coli* is still less than 10% in most parts of North America and Europe (Gupta et al, 2011).** Fluoroquinolone resistance was also associated with more frequent multidrug resistance (Karlowksy et al, 2006). More recent single-center hospital studies have found resistance patterns to be even higher, roughly 26% (Siddiqui, 2008). In a transplant unit, where fluoroquinolones are commonly administered prophylactically, *E. coli* resistance can be 80%. **Previous use of fluoroquinolones and the presence of underlying urologic diseases were the strongest determinants for UTIs caused by resistant strains (Ena et al, 1995).** Fluoroquinolone resistance is an increasing problem in some European countries. A multiple-resistant phenotype involving fluoroquinolone resistance is now present in most countries in Europe, and this phenotype is selected for not only by the use of quinolones but also by the use of ampicillin, sulfamethoxazole, and TMP-MX (Kahlmeter and Menday, 2003). This is a concern because fluoroquinolones, which are associated with chromosomal-mediated but not plasmid-mediated resistance, are the current drug of choice for patients who have been exposed to agents causing plasmid-mediated resistance.

The clinical significance of these in vitro trends in resistance has been addressed in studies that correlated in vitro resistance to TMP-SMX with clinical outcome in uncomplicated cystitis and pyelonephritis (Gupta and Stamm, 2002). Clinical failures occurred in 40% to 50% of women if the bacteria were resistant and the bacteriologic failure approached 60%. (For further information on the role of TMP-SMX in prophylaxis, see [Bladder Infections](#) later in this chapter.)

Antimicrobial Formulary

The mechanism of action, reliable coverage, and common adverse reactions, precautions, and contraindications for antimicrobial agents used in the treatment of UTIs are indicated in [Tables 12-4, 12-5, and 12-6](#), respectively.

TABLE 12-4 Mechanism of Action of Common Antimicrobials Used in the Treatment of Urinary Tract Infections

DRUG OR DRUG CLASS	MECHANISM OF ACTION	MECHANISMS OF DRUG RESISTANCE
β -Lactams (penicillins, cephalosporins, aztreonam)	Inhibition of bacterial cell wall synthesis	Production of β -lactamase Alteration in binding site of penicillin-binding protein Changes in cell wall porin size (decreased penetration)
Aminoglycosides	Inhibition of ribosomal protein synthesis	Downregulation of drug uptake into bacteria Bacterial production of aminoglycoside-modifying enzymes
Quinolones	Inhibition of bacterial DNA gyrase	Mutation in DNA gyrase-binding site Changes in cell wall porin size (decreased penetration) Active efflux
Fosfomycin	Inhibition of bacterial cell wall synthesis	Novel amino acid substitutions or the loss of function of transporters
Nitrofurantoin	Inhibition of several bacterial enzyme systems	Not fully elucidated—develops slowly With prolonged exposure
Trimethoprim-sulfamethoxazole	Antagonism of bacterial folate metabolism	Draws folate from environment (enterococci)
Vancomycin	Inhibition of bacterial cell wall synthesis (at β -lactams)	Enzymatic alteration of peptidoglycan at different point than target

TABLE 12-5 Reliable Coverage of Antimicrobials Used in the Treatment of Urinary Tract Infections of Commonly Encountered Pathogens*

ANTIMICROBIAL AGENT OR CLASS	GRAM-POSITIVE PATHOGENS	GRAM-NEGATIVE PATHOGENS
Amoxicillin or ampicillin	<i>Streptococcus</i> Enterococci	<i>Proteus mirabilis</i>
Amoxicillin with clavulanate	<i>Streptococcus</i> Enterococci	<i>P. mirabilis</i> <i>Klebsiella</i> species
Ampicillin with sulbactam	<i>Staphylococcus</i> (not MRSA) Enterococci	<i>P. mirabilis</i> <i>Haemophilus influenzae</i> , <i>Klebsiella</i> species
Antistaphylococcal penicillins	<i>Streptococcus</i> <i>Staphylococcus</i> (not MRSA)	None
Antipseudomonal penicillins	<i>Streptococcus</i> Enterococci	Most, including <i>Pseudomonas aeruginosa</i>
First-generation cephalosporins	<i>Streptococcus</i> <i>Staphylococcus</i> (not MRSA)	<i>Escherichia coli</i> <i>P. mirabilis</i> <i>Klebsiella</i> species
Second-generation cephalosporins (cefamandole, cefuroxime, cefaclor)	<i>Streptococcus</i> <i>Staphylococcus</i> (not MRSA)	<i>E. coli</i> , <i>P. mirabilis</i> <i>H. influenzae</i> , <i>Klebsiella</i> species
Second-generation cephalosporins (cefoxitin, cefotetan)	<i>Streptococcus</i>	<i>E. coli</i> , <i>Proteus</i> species (including indole-positive) <i>H. influenzae</i> , <i>Klebsiella</i> species
Third-generation cephalosporins (ceftriaxone)	<i>Streptococcus</i> <i>Staphylococcus</i> (not MRSA)	Most, excluding <i>P. aeruginosa</i>
Third-generation cephalosporins (ceftazidime)	<i>Streptococcus</i>	Most, including <i>P. aeruginosa</i>
Aztreonam	None	Most, including <i>P. aeruginosa</i>
Aminoglycosides	<i>Staphylococcus</i> (urine)	Most, including <i>P. aeruginosa</i>
Fluoroquinolones	<i>Streptococcus</i> *	Most, including <i>P. aeruginosa</i>
Nitrofurantoin	<i>Staphylococcus</i> (not MRSA) Enterococci	Many Enterobacteriaceae (not <i>Providencia</i> , <i>Serratia</i> , <i>Acinetobacter</i>) <i>Klebsiella</i> species
Fosfomycin	Enterococci	Most Enterobacteriaceae (not <i>P. aeruginosa</i>)
Pivmecillinam	None	Most, excluding <i>P. aeruginosa</i>
Trimethoprim-sulfamethoxazole	<i>Streptococcus</i> <i>Staphylococcus</i>	Most Enterobacteriaceae (not <i>P. aeruginosa</i>)
Vancomycin	All, including MRSA	None

MRSA, methicillin-resistant *Staphylococcus aureus*.

*Depends on the antimicrobial agent.

TABLE 12-6 Common Adverse Reactions, Precautions, and Contraindications for Antimicrobial Agents Used in Treatment of Urinary Tract Infection

DRUG OR DRUG CLASS	COMMON ADVERSE REACTIONS	PRECAUTIONS AND CONTRAINDICATIONS
Amoxicillin or ampicillin	Hypersensitivity (immediate or delayed) Diarrhea (especially with ampicillin), GI upset AAPMC Maculopapular rash (not hypersensitivity) Decreased platelet aggregation	Increased risk of rash with concomitant viral disease, allopurinol therapy
Amoxicillin with clavulanic acid	Increased diarrhea, GI upset with amoxicillin/clavulanic acid	
Ampicillin with sulbactam	Same as with amoxicillin/ampicillin	
Antistaphylococcal penicillins	Same as with amoxicillin/ampicillin GI upset (with oral agents) Acute interstitial nephritis (especially with methicillin)	

TABLE 12-6 Common Adverse Reactions, Precautions, and Contraindications for Antimicrobial Agents Used in Treatment of Urinary Tract Infection—cont'd

DRUG OR DRUG CLASS	COMMON ADVERSE REACTIONS	PRECAUTIONS AND CONTRAINDICATIONS
Antipseudomonal penicillins	Same as with amoxicillin/ampicillin Hypernatremia (these drugs are given as sodium salt; especially carbenicillin, ticarcillin) Local injection site reactions	Use with caution in patients very sensitive to sodium loading.
Cephalosporins	Hypersensitivity (less than with penicillins) GI upset (with oral agents) Local injection site reactions AAPMC Positive Coombs test Decreased platelet aggregation (especially with cefotetan, cefamandole, cefoperazone)	Should not be used in patients with immediate hypersensitivity to penicillins; may use with caution in patients with delayed hypersensitivity reactions
Aztreonam	Hypersensitivity (less than with penicillins)	Less than 1% incidence of cross-reactivity in penicillin- or cephalosporin-allergic patients; may be used with caution in these patients
Aminoglycosides	Ototoxicity: vestibular and auditory components Nephrotoxicity: nonoliguric azotemia Neuromuscular blockade with high levels	Avoid in pregnant patients, except in pyelonephritis. Avoid if possible in patients with severely impaired renal function, diabetes, or hepatic failure. Use with caution in myasthenia gravis patients (owing to potential for neuromuscular blockade). Use with caution with other potentially ototoxic and nephrotoxic drugs.
Fluoroquinolones	Mild GI effects; dizziness, lightheadedness; photosensitivity Central nervous system effects, including dizziness, tremors, confusion, mood disorder, hallucinations Tendon rupture	Avoid in children or pregnant patients due to arthropathic effects. Concomitant antacid, iron, zinc, or sucralfate use dramatically decreases oral absorption; use another antimicrobial agent or discontinue sucralfate use while on quinolones. Space administration of quinolones from antacids, iron, or zinc products by at least 2 hr to ensure adequate absorption. Ensure adequate patient hydration. These agents can significantly increase theophylline plasma levels (ciprofloxacin and enoxacin seem to have a greater effect than norfloxacin or ofloxacin); avoid quinolones or monitor theophylline levels closely. These agents can lower seizure threshold; avoid in patients with epilepsy and in patients with other risk factors (medications or illness) that may lower the seizure threshold. Monitor glucose levels in patients on antidiabetic agents because hypoglycemia and hyperglycemia have been reported in patients treated concurrently with fluoroquinolones and antidiabetic agents. These agents can enhance warfarin effects; closely monitor coagulation tests.
Fosfomycin	Headache GI upset Vaginitis	Hypersensitivity to fosfomycin or any component of the formulation
Pivmecillinam	Rash GI upset	Use with caution in patients with penicillin hypersensitivity.

Continued

TABLE 12-6 Common Adverse Reactions, Precautions, and Contraindications for Antimicrobial Agents Used in Treatment of Urinary Tract Infection—cont'd

DRUG OR DRUG CLASS	COMMON ADVERSE REACTIONS	PRECAUTIONS AND CONTRAINDICATIONS
Nitrofurantoin	GI upset Peripheral polyneuropathy (especially in patients with impaired renal function, anemia, diabetes, electrolyte imbalance, vitamin B deficiency, and debilitated) Hemolysis in patients with G6PD deficiency Pulmonary hypersensitivity reactions can range from acute to chronic and include cough, dyspnea, fever, and interstitial changes.	Do not use in patients with low creatinine clearance (<50 mL/min) because adequate urine concentrations will not be achieved. Monitor long-term patients closely. Avoid concomitant probenecid use, which blocks renal excretion of nitrofurantoin. Avoid concomitant magnesium or quinolones, which are antagonistic to nitrofurantoin.
Trimethoprim-sulfamethoxazole	Hypersensitivity, rash GI upset Photosensitivity Hematologic toxicity (AIDS patients)	Higher incidence of all adverse reactions occurs in AIDS patients and the elderly. Avoid in pregnant patients. Avoid in patients receiving warfarin; concomitant use can significantly elevate prothrombin time.
Vancomycin	“Red-man syndrome”: flushing, fever, chills, rash, hypotension (histaminic effect) Nephrotoxicity and/or ototoxicity when combined with other nephrotoxic and/or ototoxic drugs Local injection site reactions	Use with caution with other potentially ototoxic and nephrotoxic drugs.

AAPMC, antimicrobial-associated pseudomembranous colitis; AIDS, acquired immunodeficiency syndrome; GI, gastrointestinal; G6PD, glucose-6-phosphate dehydrogenase.

Modified from McEvoy GK, editor. American Hospital Formulary Service drug information. Bethesda (MD): American Society of Health-System Pharmacists; 1995.

Nitrofurantoin

Nitrofurantoin is effective against common uropathogens, but it is not effective against *Pseudomonas* and *Proteus* species (Iravani, 1991). It is rapidly excreted from the urine but does not obtain therapeutic levels in most body tissues, including the gastrointestinal (GI) tract. Therefore it is not useful for upper tract and complicated infections (Wilhelm and Edson, 1987). It has minimal effects on the resident bowel and vaginal flora and has been used effectively in prophylactic regimens for more than 40 years. Acquired bacterial resistance to this drug is exceedingly low. Nitrofurantoin should be used only during the first two trimesters of pregnancy. Nitrofurantoin can cause GI upset and rare pulmonary issues when used chronically. Nitrofurantoin should also be avoided in patients with suspicion of or known glucose-6-phosphate dehydrogenase (G6PD) deficiency because it can lead to hemolytic anemia.

Trimethoprim/Sulfamethoxazole

The combination of TMP-SMX has been the most widely used antimicrobial agent for the treatment of acute UTIs. TMP alone is as effective as the combination for most uncomplicated infections and may be associated with fewer side effects (Johnson and Stamm, 1989); however, the addition of SMX contributes to efficacy in the treatment of upper tract infection via a synergistic bactericidal effect and may diminish the emergence of resistance (Burman, 1986) and attains therapeutic levels in most tissues. TMP alone or in combination with SMX is effective against most common uropathogens, with the notable exception of *Enterococcus* and *Pseudomonas* species. TMP and TMP-SMX are inexpensive and have minimal adverse effects on the bowel flora. Disadvantages are relatively common adverse effects, consisting primarily of rashes and gastrointestinal complaints (Cockerill and Edson, 1991). TMP-SMX should be avoided during pregnancy.

Fosfomycin

Fosfomycin, an oral bactericidal antimicrobial agent similar to phosphonic acid in chemical structure, is active against most uropathogens. Its major benefit is its limited cross-resistance between most other common antibacterial agents, as well as its efficacy against the majority of gram-negative organisms and vancomycin-resistant *Enterococcus* (VRE). Further, it has been shown to be effective as a single-dose agent when used as an empirical treatment for uncomplicated cystitis. It is generally well tolerated with low incidences of GI upset and headache and very rare adverse events seen in multiple trials (Patel et al, 1997).

Fluoroquinolones

Fluoroquinolones share a common predecessor in nalidixic acid and inhibit DNA gyrase, a bacterial enzyme integral to replication. The fluoroquinolones have a broad spectrum of activity that makes them ideal for the empirical treatment of UTIs. They are highly effective against Enterobacteriaceae, as well as *P. aeruginosa*. Activity is also high against *S. aureus* and *S. saprophyticus*, but, in general, antistreptococcal coverage is marginal. Most anaerobic bacteria are resistant to these drugs; therefore the normal vaginal and bowel flora are not altered (Wright et al, 1993). Bacterial resistance initially appeared to be uncommon, but it is being reported at an increasing rate because of indiscriminate use of these agents (Wright et al, 1993; Vromen et al, 1999).

These drugs are not nephrotoxic, but renal insufficiency prolongs the serum half-life, requiring adjusted dosing in patients with creatinine clearances of less than 30 mL/min. Adverse reactions are uncommon; gastrointestinal disturbances are more common. Hypersensitivity, skin reactions, mild central and peripheral nervous system reactions, and even acute renal failure have been reported (Hootkins et al, 1989). Achilles tendon disorders,

including rupture, have been estimated to occur in 20 cases per 100,000 and therefore fluoroquinolone use should be discontinued at the first sign of tendon pain (Greene, 2002). The mechanism of tendon rupture is unclear, but ciprofloxacin stimulates matrix-degrading protease activity from fibroblasts and exerts an inhibitory effect on fibroblast metabolism and synthesis of matrix ground substance, factors that may contribute to tendinopathy (Williams et al, 2000). Administration of the fluoroquinolones to immature animals has caused damage to the developing cartilage; therefore they are currently contraindicated in children, adolescents, and pregnant or nursing women (Christ et al, 1988). There are important drug interactions associated with the fluoroquinolones. The World Health Organization (WHO) warns of rare increases in the anticoagulant effects of Coumadin when taken with fluoroquinolones. Antacids containing magnesium or aluminum interfere with absorption of fluoroquinolones (Davies and Maesen, 1989). Certain fluoroquinolones (enoxacin and ciprofloxacin) elevate plasma levels of theophylline and prolong its half-life (Wright et al, 1993). For most uncomplicated UTIs, the fluoroquinolones have been only slightly more effective than TMP-SMX. However, as resistance to TMP-SMX increases, the fluoroquinolones have distinct advantages in empirical treatment of patients recently exposed to antimicrobial agents and in the outpatient treatment of complicated UTIs (Dalkin and Schaeffer, 1988; Gupta et al, 1999). They may be considered as first-line agents in areas where a significant level of resistance (>20%) exists (in common bacteria) to agents such as ampicillin and TMP-SMX.

Cephalosporins

All three generations of cephalosporins have been used for the treatment of acute UTIs (Wilhelm and Edson, 1987). In general, as a group, activity is high against Enterobacteriaceae and poor against enterococci. First-generation cephalosporins have greater activity against gram-positive organisms, as well as common uropathogens such as *E. coli* and *Klebsiella pneumoniae*, whereas second-generation cephalosporins have activity against anaerobes. Third-generation cephalosporins are more reliably active against community-acquired and nosocomial gram-negative organisms than other β -lactam antimicrobials. Selective pressure engendered by these broad-spectrum agents should limit their use to complicated infections and situations in which parenteral therapy is required and resistance to standard antimicrobial agents is likely. They are also safe for use during pregnancy.

Aminopenicillins

Ampicillin and amoxicillin have been used often in the past for the treatment of UTIs, but the emergence of resistance in 40% to 60% of common urinary isolates has lessened the usefulness of these drugs (Hooton and Stamm, 1991; Gupta et al, 2011). The effects of these agents on the normal bowel and vaginal flora can predispose patients to reinfection with resistant strains and often lead to candidal vaginitis (Irvani, 1991). The addition of the β -lactamase inhibitor clavulanate to amoxicillin greatly improves activity against β -lactamase-producing bacteria resistant to amoxicillin alone. However, its high cost and frequent gastrointestinal side effects limit its usefulness. The extended-spectrum penicillin derivatives (e.g., pivmecillinam, piperacillin, mezlocillin, azlocillin) retain ampicillin's activity against enterococci and offer activity against many ampicillin-resistant gram-negative bacilli. This makes them attractive agents for use in patients with nosocomially acquired UTIs and as the initial parenteral treatment of acute uncomplicated pyelonephritis acquired outside of the hospital, although less expensive agents are equally effective.

Aminoglycosides

When combined with TMP-SMX or ampicillin, aminoglycosides are the first drugs of choice for febrile UTIs. Their nephrotoxicity and ototoxicity are well recognized; hence, careful monitoring of

patients for renal and auditory impairment associated with infection is indicated. Once-daily aminoglycoside regimens have been instituted to maximize bacterial killing by optimizing the peak concentration-to-minimal inhibitory concentration ratio and reduce the potential for toxicity (Fig. 12-11) (Nicolau et al, 1995). Administering an aminoglycoside as a single daily dose can take advantage not only of its concentration-dependent killing ability but also of two other important characteristics: time-dependent toxicity and a more prolonged postantimicrobial effect (Gilbert, 1991; Zhanel et al, 1991). The regimen consists of a fixed 7 mg/kg dose of gentamicin or 5 to 7 mg/kg tobramycin. Subsequent interval adjustments are made by using a single concentration in serum and a nomogram designed for monitoring of once-daily therapy (Fig. 12-12). Antimicrobial doses are given at the interval determined by the drug concentration of a sample obtained after the start of the initial infusion. For example, if the serum concentration was 7 $\mu\text{g/mL}$ 10 hours after the start of the infusion, subsequent 7-mg/kg doses would be given every 36 hours. This regimen is

Figure 12-11. Simulated concentration-versus-time profile of once-daily (7 mg/kg/24 hr) and conventional (1.5 mg/kg/8 hr) regimens for patients with normal renal function. (From Nicolau DP, Freeman CD, Belliveau PP, et al. Experience with a once-daily aminoglycoside program administered to 2,184 adult patients. *Antimicrob Agents Chemother* 1995;39:650-5.)

Figure 12-12. Once-daily aminoglycoside nomogram for gentamicin and tobramycin at 7 mg/kg. (From Nicolau DP, Freeman CD, Belliveau PP, et al. Experience with a once-daily aminoglycoside program administered to 2,184 adult patients. *Antimicrob Agents Chemother* 1995;39:650-5.)

clinically effective, reduces the incidence of nephrotoxicity, and provides a cost-effective method for administering aminoglycosides by reducing ancillary service times and serum aminoglycoside determinations.

Aztreonam

Aztreonam has a similar spectrum of activity as the aminoglycosides, and as with all β -lactams, it is not nephrotoxic. However, its spectrum of activity is less broad than the third-generation cephalosporins. It should be used primarily in patients who have penicillin allergies.

Pivmecillinam

Pivmecillinam is a penicillin-like β -lactam antibiotic which is the prodrug of mecillinam. It has high activity against gram-negative organisms and is primarily used in Nordic countries for empirical treatment of uncomplicated cystitis. **It is not currently available in the United States**, but it has been shown to have low resistance patterns (roughly 2% of *E. coli*) as well as being safe and effective (Graninger, 2003).

Choice of Antimicrobial Agents

Many antimicrobial agents have been shown to be effective in the treatment of UTIs. **Factors important in aiding selection of empirical therapy include whether the infection is complicated or uncomplicated; the spectrum of activity of the drug against the probable pathogen; a history of hypersensitivity; potential side effects, including renal and hepatic toxicity; and cost.** In addition, favorable or unfavorable effects of the antimicrobial agent on the vaginal and bowel flora are important in women with recurrent UTIs. The bacterial susceptibility and cost of the drug vary dramatically among inpatient and outpatient settings throughout the country. It is imperative, therefore, that each clinician keep abreast of changes in bacterial susceptibility and cost and use current information when choosing antimicrobial agents.

Duration of Therapy

The duration of therapy needed to cure a UTI appears to be related to a number of variables, including the extent and duration of tissue invasion, the bacterial concentration in urine, the achievable urine concentration of the antimicrobial agent, and risk factors (see later) that impair the host and natural defense mechanisms.

KEY POINTS: PRINCIPLES OF ANTIMICROBIAL THERAPY

- Effective antimicrobial therapy must eliminate bacterial growth in the urinary tract.
- Antimicrobial resistance is increasing because of excessive utilization.
- Antimicrobial selection should be influenced by efficacy, safety, cost, and compliance.

ANTIMICROBIAL PROPHYLAXIS FOR COMMON UROLOGIC PROCEDURES

Principles

Surgical antimicrobial prophylaxis entails treatment with an antimicrobial agent before and for a *limited* time after a procedure to prevent local or systemic postprocedural infections. For most procedures, prophylaxis should be initiated between 30

minutes and 120 minutes before the procedure (Bratzler and Houck, 2004). Efficacious levels should be maintained for the duration of the procedure and, in special circumstances, a limited time (24 hours, at most) after the procedure (Bratzler and Houck, 2004). Although prospective studies addressing prophylaxis for urologic procedures exist, most focus on only a narrow spectrum of procedures. However, application of the principles of these studies with additional consideration of both the patient and the type of procedure provides a framework for determining when and what type of antimicrobial prophylaxis may be indicated. An additional, nontraditional type of prophylaxis in urology entails periprocedural treatment of the urinary tract with an antimicrobial agent to prevent local or systemic sequelae from the manipulation of colonized hardware such as a stent or urethral catheter.

A wide array of patients undergo invasive procedures in urology. The ability of a host to respond to bacteriuria or bacteremia and the sequelae of a possible infection are two important considerations when assessing the need for antimicrobial prophylaxis. Factors that affect the host's ability to respond to infection include advanced age, anatomic anomalies, poor nutritional status, smoking, chronic corticosteroid use, other concurrent medication use, and immunodeficiencies such as untreated HIV infection (Box 12-5). Additionally, chronic indwelling hardware, infected endogenous material such as stones, distant infectious sites, and prolonged hospitalizations also increase the risk of infectious complications by increasing the local bacterial concentration and/or altering the spectrum of bacterial flora. The potential seeding of artificial heart valves or prosthetic joints increases the sequelae of a systemic infection in hosts who otherwise may not be at an increased risk of infection. Thus a thorough history and examination of the patient is crucial in directing antimicrobial prophylaxis before a urologic procedure.

The type of procedure will also help direct the timing, duration, and spectrum of antimicrobial prophylaxis needed (see Table 12-7 for a summary of antimicrobial prophylaxis recommendations). Consideration should be given to the extent of the local tissue injury incurred and the anticipated type of flora at the site.

Antimicrobial prophylaxis is not without morbidity because allergic complications, although rare, may result in minor reactions such as rash or gastric disturbances or significant sequelae such as early withdrawal of therapy, allergic nephritis, or anaphylaxis.

Urethral Catheterization and Removal

The indications for the routine use of prophylactic antimicrobial agents before urethral catheterization vary and depend on the health, sex, and specific living circumstances of the individual

BOX 12-5 Host Factors That Increase the Risk of Infection

Advanced age
Anatomic anomalies
Poor nutritional status
Smoking
Chronic corticosteroid use
Immunodeficiency
Chronic indwelling hardware
Infected endogenous/exogenous material
Distant coexistent infection
Prolonged hospitalization

Data from Cruse PJ. Surgical wound infection. In: Wonsiewicz MJ, editor. Infectious disease. Philadelphia: WB Saunders; 1992. p. 758–64; and Mangram AJ, Horan TC, Pearson ML, et al. Guideline for prevention of surgical site infection, 1999. Hospital Infection Control Practices Advisory Committee. Infect Control Hosp Epidemiol 1999;20:250–78; quiz 279–80.

patient, as well as the indication for catheterization (Schaeffer 2006). The risk of infection after one-time urethral catheterization is 1% to 2% in healthy domiciliary women; however, this risk rises significantly in hospitalized patients (Turck et al, 1962; Thiel and Spuhler, 1965). Thus, for patients with risk factors for infection (see Box 12-5), antimicrobial prophylaxis with an oral agent such as TMP-SMX or a fluoroquinolone should decrease the risk of postprocedural infection (see Table 12-7).

Prolonged use of an indwelling urethral catheter is common in hospitalized patients and is associated with an increased risk of bacterial colonization, with a 3% to 10% incidence of bacteriuria per catheter day in one study and 100% incidence of bacteriuria

with long-term catheterization (>30 days) (Kass, 1956; Nickel et al, 1985; Liedl, 2001). Prophylactic administration of antimicrobial agents during catheterization is not generally recommended because bacterial resistance can develop rapidly and complicate subsequent antimicrobial treatment (Clarke et al, 2005). This is supported by the Cochrane Database of Systematic Reviews that concluded that antimicrobials given postprocedurally until removal or for the first three postoperative days did not reduce rates of bacteriuria or infection (Niël-weise and van den Broek, 2005).

The natural history of bacteriuria after catheter removal has not been comprehensively studied. Harding and associates (1991) reported that in asymptomatic bacteriuric women who had been

catheterized for 4 to 6 days, 25% developed a UTI within 14 days of catheter removal. In this study, 1-day treatment with TMP-SMX was as effective as a 10-day course at resolving infections. Similar studies on the natural history of postcatheterization bacteriuria have not been performed in male patients. Note that antimicrobial treatment before removal of an indwelling catheter in a patient suspected of having bacteriuria is not considered prophylaxis but rather is treatment for a presumptive UTI; duration of treatment generally should follow previously outlined guidelines for uncomplicated or complicated UTIs.

Data from Polastri and colleagues (1990) suggest that antimicrobial prophylaxis for chronic indwelling catheter changes is not indicated. In their study of 46 catheter changes, bacteremia occurred 4% of the time and, when noted, was associated with very low concentrations of bacteria in the cultures. Systemic sequelae were not noted.

Urodynamics

Urodynamics, like cystoscopy, is a minimally traumatic procedure with limited urothelial injury that poses a small risk of local infection in hosts with normal anatomy and immune response. Several recent studies support this notion. In a series of women with urinary incontinence randomized to receive 1 day of nitrofurantoin or placebo, Cundiff and coworkers (1999) noted no difference in postprocedural UTI (5% vs. 7%) 1 week after evaluation. Similarly, Peschers and associates (2001) reported infections 1 week after multichannel urodynamics in 5% and 6% in nondiabetic women

treated with placebo or co-trimoxazole. Conversely, Kartal and colleagues (2006) demonstrated a reduction in UTIs from 14% to 1% with administration of a single dose of ciprofloxacin in a blinded 192-patient trial. Most series examining the use of antimicrobial prophylaxis exclude patients with altered anatomy such as large prostates or comorbidities, including neurogenic bladder, spinal cord injury, or diabetes, all factors that increase the risk of infection. This is illustrated in work performed by Payne and colleagues in which frequencies of bacteriuria after urodynamics were much higher in men (36%) compared with the women studied (15%) (Payne et al, 1988). In sum, antimicrobial prophylaxis should be considered for patients with a more complex clinical history or anatomy such as men with large postvoid residuals or spinal cord-injured patients.

Transrectal Ultrasound-Guided Prostate Biopsy

The use of prophylactic antimicrobials for transrectal ultrasound-guided prostate (TRUSP) biopsy reduces postprocedural fever and UTI in most studies. The class and duration of antimicrobial treatment are more varied and controversial. Antimicrobial prophylaxis with fluoroquinolones has been shown to significantly reduce the rates of infectious complications compared to placebo (8% vs. 25%) (Sieber et al, 1997; Taylor and Bingham, 1997a, 1997b; Kapoor et al, 1998; Shandera et al, 1998; Tal et al, 2003; Zani et al, 2011).

However, several recent studies have highlighted an increasing trend of infectious complications caused by fluoroquinolone-resistant organisms among men undergoing TRUSP (Binsaleh

et al, 2004; Han et al, 2005; Feliciano et al, 2008; Ng and Chan, 2008; Lange et al, 2009; Young et al, 2009; Zaytoun et al, 2011). Prevalence rates for colonization with fluoroquinolone-resistant organisms in this patient population have been reported to be as high as 22% (Liss et al, 2011). Nevertheless more than 90% of urologists continue to use fluoroquinolones empirically for antimicrobial prophylaxis before TRUSP (Shandera et al, 1998). The increasing prevalence of infectious complications with fluoroquinolone-resistant bacteria in men undergoing TRUSP suggests that this approach may be injudicious for some patients (Taylor et al, 2012). Indeed, of fluoroquinolone-resistant strains obtained by rectal swabs of men prior to prostate biopsy, 70% were ST131 isolates (Liss et al, 2013). See *Urinary Pathogens* earlier in chapter for more in-depth information on ST131 and resistance.

Empiric prophylaxis with a combination of aminoglycosides and fluoroquinolones has been effective in recent studies (Kehinde et al, 2013; Ho et al, 2009), but it is inevitable that this approach will also eventually fail because of antimicrobial resistance. **Rectal swab culture obtained before TRUSP allows for the isolation and identification of fluoroquinolone-resistant organisms from a patient's native intestinal flora.** In a study using targeted prophylaxis based on bacterial sensitivities of rectal swabs prior to TRUSP, 19.6% of men had fluoroquinolone-resistant organisms. There were no infectious complications in the men who received targeted prophylaxis, while there were infectious complications, including sepsis, in 2.6% on empiric prophylaxis (Taylor et al, 2012). Cost-effectiveness analysis revealed that targeted prophylaxis yielded a cost savings of \$4,499 per post TRUSP infectious complication averted. Per estimation, 38 men would need to undergo rectal swab before TRUSP to prevent one infectious complication. Thus a benefit to screening before TRUSP and targeted prophylaxis should be considered as a thoughtful, predictable alternative to empiric prophylaxis.

Recent studies suggest a single-dose/day of fluoroquinolones is as effective as 3 days of treatment (Sabbagh et al, 2004). Together these data suggest that a minimum of 1 day of an antimicrobial agent is indicated for transrectal ultrasound-guided prostate biopsies.

Shockwave Lithotripsy

The incidence of UTIs after shockwave lithotripsy is reported to range from 0% to 28% without antimicrobial prophylaxis. A recent meta-analysis of contemporary randomized controlled trials examined the utility and cost-effectiveness of antimicrobial prophylaxis for shockwave lithotripsy and demonstrated, in individuals with sterile preprocedure urine cultures, a reduction in the rate of UTIs after shockwave lithotripsy from 5.7% to 2.1% (Pearle and Roehrborn, 1997). This analysis also demonstrated cost-effectiveness of prophylaxis when consideration was given for the treatment of the rare but more morbid complications of urosepsis and pyelonephritis. A history of a recent UTI or of infection stones should warrant a full treatment course of antimicrobial agents before shockwave lithotripsy.

Endoscopic Procedures: Lower Urinary Tract

Cystoscopy

Cystoscopy is a minimally traumatic procedure with limited urothelial injury performed on a diverse spectrum of patients, including young healthy women and older men. Several prospective trials (Manson, 1988; Clark and Higgs, 1990; Burke et al, 2002) of patients with preprocedure sterile urine report culture-proven rates of UTI between 2.2% and 7.8% after cystoscopy without antimicrobial prophylaxis. In Clark's report the risk of infection was higher in patients with a previous history of UTI. In a similarly designed study, Rane and colleagues (2001) reported a significantly higher postprocedure culture-proven infection rate of 21% without antimicrobial prophylaxis. More recently, Johnson and colleagues (2007) reported a randomized controlled trial of over 2000 patients that demonstrated reductions in bacteriuria with administration of

single-dose trimethoprim or ciprofloxacin. In all the studies, single doses of antimicrobial agents reduced infections to between 1% and 5%. In none of these studies were significant systemic infections reported after the cystoscopic procedures.

Together these studies illustrate two key concepts: (1) despite appropriate periprocedural preparation, a small inoculum of bacteria is likely introduced into the bladder during cystoscopy, and (2) the significance of the bacteriuria is dependent on host factors, including the ability to mount an appropriate immune response to bacterial inoculation and the ability to clear the bacterial inoculation. For example, in a man with urinary retention, a small inoculum of bacteria could persist and divide in the retained fraction of urine and result in a symptomatic infection. In a host with a reduced ability to respond to infection, this bacteriuria could become significant. In contrast, a middle-aged woman undergoing cystoscopy for microscopic hematuria is more likely to efficiently empty her bladder and clear the inoculum but may be exposed to an increased inoculum of bacteria if inappropriately prepared for the examination. **Thus we recommend prophylaxis when aberrant host factors could increase the probability or significance of an infection** (see Table 12-7). A single dose of a fluoroquinolone is commonly used but other agents such as trimethoprim have also been utilized.

Transurethral Resection of the Prostate and Bladder

Therapeutic transurethral lower urinary tract procedures increase the risk of localized infections compared with simple diagnostic cystoscopy. Although not delineated in any prospective studies, several risk factors likely increase infectious complications, including trauma to the mucosa, increased duration and/or degree of difficulty of the procedure, pressurized irrigants, and manipulation or resection of infected material. The most well-studied lower urinary tract procedure is **transurethral resection of the prostate**. In a meta-analysis of 32 studies (Berry and Barratt, 2002), a risk reduction was noted in bacteriuria from 26% to 9% on postoperative urine cultures obtained 2 to 5 days after the procedure for patients treated with prophylactic antimicrobial agents. Similarly, septicemia (defined as rigors, persistently elevated temperature [$>38.5^{\circ}\text{C}$], and an elevated C-reactive protein level) decreased from 4.4% to 0.9% with antimicrobial prophylaxis. The most effective antimicrobial classes included fluoroquinolones, aminoglycosides, cephalosporins, and TMP-SMX. **Single doses of antimicrobial agents did lower the relative risk of bacteriuria but not as significantly as antimicrobial agents administered for short courses (2 to 5 days) while the urethral catheter remained in place.** Although continuation of antimicrobial therapy while the catheter is in place is not truly prophylaxis, continuation of the initial prophylactic antimicrobial agent for an anticipated short period of time (with catheter in place) does not increase the risk of developing antimicrobial-resistant organisms. No recent trials have investigated prophylaxis for **transurethral resection of bladder tumors**; however, evidence from transurethral resection of the prostate procedures would suggest that prophylaxis would reduce bacteriuria in these procedures.

Patients who are known preoperatively to have UTIs should have the infections eradicated before the procedure is started; hence, in these patients, preoperative antimicrobial agents are therapeutic and not prophylactic. Failure to eradicate bacteriuria results in bacteremia in 50% of patients (Morris et al, 1976).

Diagnostic and therapeutic upper tract studies that are performed with pressurized irrigants may induce urothelial injury. Prophylaxis with antimicrobial agents that cover uropathogens is indicated.

Endoscopic Procedures: Upper Urinary Tract

Ureteroscopy

Diagnostic and therapeutic upper tract endoscopic procedures have an increased risk of localized infections compared with simple diagnostic cystoscopy because of several factors, including increased

trauma to the mucosa, increased duration and/or degree of difficulty of most ureteroscopic procedures, increased pressure of irrigants, and (when applicable) manipulation or resection of infected material. The use of antimicrobial prophylaxis is supported by a randomized trial by Knopf and colleagues (2003) in which prophylactic fluoroquinolone administration significantly reduced post-procedure UTIs in a healthy population of individuals with ureteral stones and uninfected preoperative urine. If an infection or infectious material is suspected, culture and a full treatment course of an appropriate antimicrobial are recommended before the procedure. Some urologists advocate for medical diuresis during the procedure with furosemide.

Percutaneous Procedures

Percutaneous renal surgery is commonly performed for large renal stones, ureteropelvic junction obstruction, and transitional cell carcinoma surveillance. Pyrexia and bacteremia occur frequently and likely stem from a combination of renal parenchymal injury, pressurized irrigation, and, in some cases, manipulation of infectious stones. Several studies demonstrated a relationship between the risk of postoperative infectious complications (including bacteriuria and sepsis) and the duration of the procedure and amount of irrigant used (Dogan et al, 2002). If preoperative urine cultures are positive, treatment of the infection should occur before surgery. Conversely, if preoperative cultures are negative, antimicrobial prophylaxis covering common urinary pathogens should be instituted (Wolf et al, 2008) (see Table 12-7).

Open and Laparoscopic Surgery

Open surgical procedures can be classified as clean, clean contaminated, contaminated, and dirty (Table 12-8). Antimicrobial prophylaxis is indicated for clean contaminated and contaminated wounds, whereas antimicrobial treatment with an appropriate agent should be instituted for dirty-infected wounds. To date, no large studies have evaluated the risk of surgical site infections for different laparoscopic urologic procedures. However, data in the general surgery literature suggest that the laparoscopic approach lowers the risk of surgical site infections (Kluytmans, 1997). Clean surgeries in urology include radical nephrectomy if the urinary tract is not entered. All urologic procedures in which the urinary tract

is opened electively are considered clean contaminated procedures, whereas entry into an infected urinary tract is considered a contaminated procedure and carries a higher rate of surgical site infection (Cruse, 1992). Antimicrobial agents should be active against the most likely infecting organism and should be administered within 1 hour of the procedure and discontinued 24 hours after because several studies have failed to demonstrate beneficial effects of long courses of prophylaxis (Conte et al, 1972; Goldmann et al, 1977). In the United States, first-generation cephalosporins are commonly used for prophylaxis of clean contaminated procedures because they have low incidences of allergic reactions, long half-lives, and low cost. For patients with a β -lactam allergy, the 2004 National Surgical Infection Prevention Project (NSIPP) guidelines recommend either vancomycin or clindamycin. Prophylaxis for urinary reconstruction with intestine requires increased anaerobic coverage, and thus use of second-generation cephalosporins is recommended (Bratzler and Houck, 2004). When use of the colon or appendix is anticipated for urologic reconstruction, the 2004 NSIPP recommendations include orally administered antimicrobial bowel preparation (neomycin plus erythromycin or neomycin plus metronidazole) 18 to 24 hours before surgery and parenteral cefotetan or cefoxitin 30 to 60 minutes before incision (Bratzler and Houck, 2004). Recommendations for patients with a β -lactam allergy include clindamycin plus gentamicin, aztreonam, or ciprofloxacin. Dirty wounds in urology include all abscesses and traumatic perforation of the genitourinary tract. Treatment of a dirty wound should begin with broad coverage of anticipated organisms and intraoperative wound cultures. Subsequent therapy and treatment duration depends on the sensitivities of the cultured organism.

Special Considerations

Patients with Risk of Endocarditis

The risk of infectious endocarditis (IE) after urologic procedures is low. Previous guidelines from the American Heart Association (AHA) had recommended routine prophylaxis, but the current recommendation is that the use of prophylactic antibiotics solely to prevent IE is **not recommended** (Wilson et al, 2007). However, these guidelines do acknowledge that instrumentation of the GU tract may result in transient enterococcal bacteremia. The evidence supporting this claim is anecdotal, and no data exist to demonstrate either a conclusive link between this bacteremia and IE or that administration of antimicrobial prophylaxis prevents IE. Regardless, the guidelines do state that for patients with certain concomitant conditions (prosthetic cardiac valve, previous IE, congenital heart disease, cardiac transplantation) and an active infection or colonization who are to undergo GU tract manipulation, including elective cystoscopy, antibiotic therapy to sterilize the urine may be reasonable (Class IIb evidence). Amoxicillin or ampicillin is suggested as a first-line agent for enterococci, vancomycin for those who cannot tolerate ampicillin, or culture-directed agents as possible (Wilson et al, 2007).

Patients with Indwelling Orthopedic Hardware

Bacterial seeding of implanted orthopedic hardware is a rare but morbid event. A joint commission of the American Urological Association (AUA), the American Academy of Orthopaedic Surgeons (AAOS), and infectious disease specialists convened in 2003 and released an advisory statement on antimicrobial prophylaxis for urologic patients with total joint replacement (American Urological Association and American Academy of Orthopaedic Surgeons, 2003) (Table 12-9). In general, antimicrobial prophylaxis for urologic patients with total joint replacements, pins, plates, or screws is not indicated. Prophylaxis is advised for individuals at higher risk of seeding a prosthetic joint, including those with recently inserted implants (within 2 years) and/or host risk factors as delineated earlier. Prophylaxis on the basis of potential seeding of a prosthetic joint should be instituted for procedures

TABLE 12-8 Surgical Wound Classification

TERM	DESCRIPTION
Clean	Uninfected wound without inflammation or entry into the genital, urinary, or alimentary tract Primary wound closure \pm closed drainage
Clean contaminated	Uninfected wound with controlled entry into the genital, urinary, or alimentary tract Primary wound closure \pm closed drainage
Contaminated	Uninfected wound with major break in sterile technique (gross spillage from gastrointestinal tract or nonpurulent inflammation) Open fresh accidental wounds
Dirty infected	Wound with preexisting clinical infection or perforated viscera Old traumatic wounds with devitalized tissue

Modified from Mangram AJ, Horan TC, Pearson ML, et al. Guideline for prevention of surgical site infection, 1999. Hospital Infection Control Practices Advisory Committee. Infect Control Hosp Epidemiol 1999;20:250-78; quiz 279-80.

TABLE 12-9 Antimicrobial Regimens for Patients with Indwelling Orthopedic Hardware

PATIENT TYPE	ANTIMICROBIAL RECOMMENDATION
Total joint inserted >2 yr ago, pins, plates, screws + no host risk factors	Not recommended empirically
Total joint inserted <2 yr ago or aberrant host factor(s)	Oral quinolone or ampicillin, 2 g IV + gentamicin, 1.5 mg/kg IV, 30-60 min before procedure Substitute vancomycin, 1 g IV, over 1-2 hr before procedure if ampicillin allergy

From American Urological Association and American Academy of Orthopaedic Surgeons. Antibiotic prophylaxis for urological patients with total joint replacements. *J Urol* 2003;169:1796-7.

including stone manipulation, transmural incision of the urinary tract, upper tract endoscopic procedures, procedures involving bowel segments, and transrectal prostate biopsy. Additionally, patients with recent prosthetic joints or compromised host factors and urinary diversions, indwelling stents or catheters, a recent history of urinary retention, or UTIs should receive antimicrobial prophylaxis before urinary tract procedures. The AUA Advisory Statement recommends for these patients either an oral quinolone or ampicillin, 2 g intravenous (IV) (vancomycin, 1 g IV over 1 to 2 hours for ampicillin-allergic patients), and gentamicin, 1.5 mg/kg IV, 30 to 60 minutes before the procedure.

KEY POINTS: ANTIMICROBIAL PROPHYLAXIS FOR COMMON UROLOGIC PROCEDURES

- Antimicrobial prophylaxis entails treatment with an antimicrobial agent before and for a limited time after a procedure to prevent local or systemic postprocedural infections.
- The type of procedure and competency of the host defenses determine the need for antimicrobial prophylaxis.
- Special considerations for antimicrobial prophylaxis include patients undergoing TRUSP, those with a risk of endocarditis, and patients with indwelling orthopedic hardware.

BLADDER INFECTIONS

Uncomplicated Cystitis

Most cases of uncomplicated cystitis occur in women. Each year, approximately 10% of women report having had a UTI and more than 50% of all women have at least one such infection in their lifetime (Foxman et al, 2000). Uncomplicated cystitis occasionally occurs in prepubertal girls, but it increases greatly in incidence in late adolescence and during the second and fourth decades of life. Twenty-five to 30 percent of women 20 to 40 years of age have a history of UTIs (Kunin, 1987). Although it is much less common, young men may also experience acute cystitis without underlying structural or functional abnormalities of the urinary tract (Krieger et al, 1993). Risk factors (Box 12-6) include sexual intercourse and use of spermicides (Hooton et al, 1996; Foxman, 2002; Handley et al, 2002). Sexual transmission of uropathogens has been suggested by demonstrating identical *E. coli* in the bowel and urinary flora of sex partners (Johnson and Stamm, 1989).

BOX 12-6 Risk Factors for Urinary Tract Infections

REDUCED URINE FLOW

Outflow obstruction, prostatic hyperplasia, prostatic carcinoma, urethral stricture, foreign body (calculus)
Neurogenic bladder
Inadequate fluid uptake (dehydration)

PROMOTE COLONIZATION

Sexual activity—increased inoculation
Spermicide—increased binding
Estrogen depletion—increased binding
Antimicrobial agents—decreased indigenous flora

FACILITATE ASCENT

Catheterization
Urinary incontinence
Fecal incontinence
Residual urine with ischemia of bladder wall

Clinical Presentation

The presenting symptoms of cystitis are variable but usually include dysuria, frequency, and/or urgency (Fig. 12-13). Suprapubic pain, hematuria, or foul-smelling urine may develop. The probability of cystitis in a woman with these symptoms alone or in combination is 50% to 90%, respectively (Bent et al, 2002). When a woman who previously has had cystitis has symptoms suggesting a recurrence, the probability that an infection is present is about 90% (Gupta et al, 2001). By definition, acute cystitis is a superficial infection of the bladder mucosa, so fever, chills, and other signs of dissemination are not present. Some patients may experience suprapubic tenderness, but most have no diagnostic physical findings. In women, physical examination should include the possibility of vaginitis, herpes, and urethral pathology, such as a diverticulum.

A remarkably narrow spectrum of etiologic agents with highly predictable profiles of antimicrobial susceptibility causes infections in young women with acute uncomplicated cystitis. *E. coli* is the causative organism in 75% to 90% of cases of acute cystitis in young women (Latham et al, 1983; Ronald, 2002). *S. saprophyticus*, a commensal organism of the skin, is the second most common cause of acute cystitis in young women, accounting for 10% to 20% of these infections (Jordan et al, 1980). Other organisms less commonly involved include *Klebsiella* and *Proteus* species and *Enterococcus*. In men, *E. coli* and other Enterobacteriaceae are the most commonly identified organisms.

Laboratory Diagnosis

The presumptive laboratory diagnosis of acute cystitis is based on microscopic urinalysis, which indicates microscopic pyuria, bacteriuria, and occasionally hematuria. Indirect dipstick tests for bacteria (nitrite) or pyuria (leukocyte esterase) may also be informative and more convenient but are less sensitive than microscopic examination of the urine. Dipsticks are most accurate when the presence of either nitrite or leukocyte esterase is considered a positive result. Urine culture remains the definitive test; and in symptomatic patients, the presence of 10^2 cfu/mL or more of urine usually indicates infection (Stamm et al, 1982b). However, as previously discussed, different thresholds are needed based on different clinical situations.

However, routine urine cultures are often not necessary. It is generally more cost-effective to manage many patients who have symptoms and urinalysis findings characteristic of uncomplicated cystitis without an initial urine culture because treatment decisions

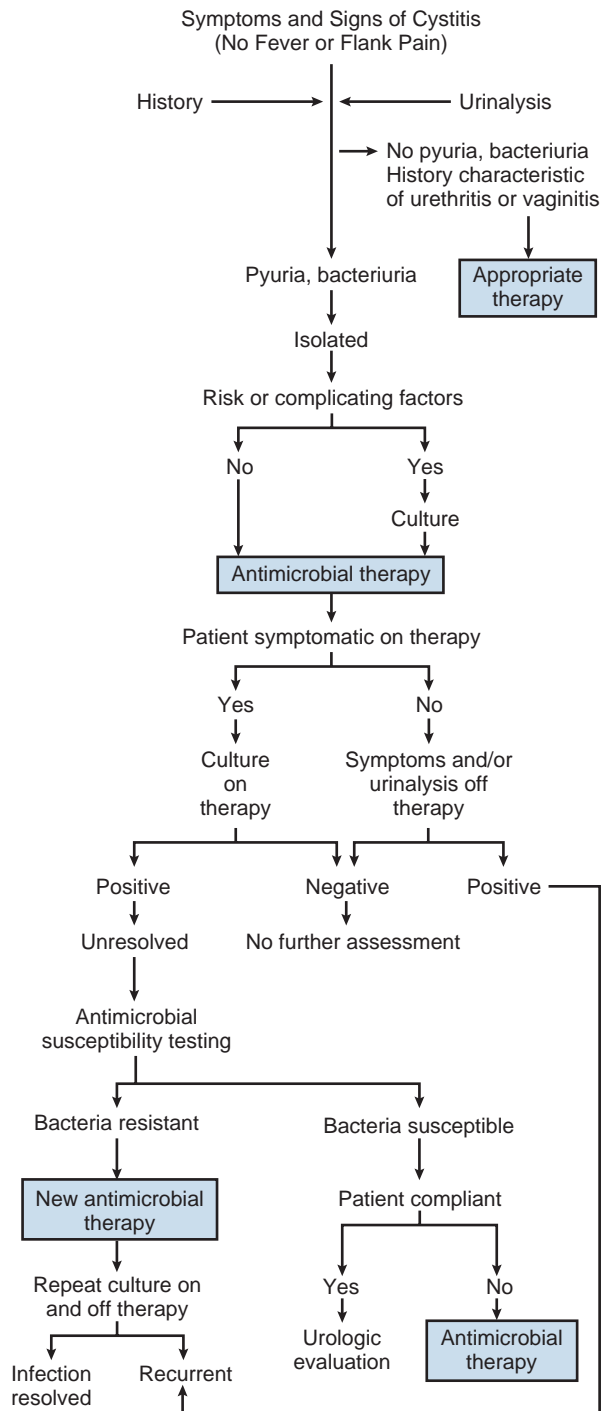

Figure 12-13. Management of acute cystitis.

are usually made and therapy is often completed before culture results are known (Komaroff, 1986). This position was supported by a cost-effectiveness study (Carlson and Mulley, 1985) in which it was estimated that the routine use of pretherapeutic urine cultures for lower UTI increases costs by 40% but decreases the overall duration of symptoms by only 10%.

Thus, in women with recent onset of symptoms and signs suggesting acute cystitis and in whom factors associated with upper tract or complicated infection are absent, a urinalysis that is positive for pyuria, bacteriuria, or hematuria, or a combination should provide sufficient documentation of UTI, and a urine culture may be omitted (McIsaac et al, 2002). A urine culture should be obtained for patients in whom symptoms and urine examination findings leave the diagnosis of cystitis in doubt. Pretherapeutic cultures and susceptibility tests are also essential

in the management of patients with recent antimicrobial therapy or UTI. In these situations, various pathogens may be present and antimicrobial therapy is less predictable and must be tailored to the individual organism (Stamm, 1986).

Differential Diagnosis

Cystitis must be differentiated from other inflammatory infectious conditions in which dysuria may be the most prominent symptom, including vaginitis, urethral infections caused by sexually transmitted pathogens, and miscellaneous noninflammatory causes of urethral discomfort (Komaroff, 1984). Characteristic features of the history, physical examination, and voided urine or other specimens allow patients with dysuria to be assigned to one of these diagnostic categories. **Vaginitis** is characterized by irritative voiding associated with vaginal irritation and is subacute in onset. A history of vaginal discharge or odor and multiple or new sexual partners is common. Frequency, urgency, hematuria, and suprapubic pain are not present. Physical examination reveals a vaginal discharge, and examination of vaginal fluid demonstrates inflammatory cells. Differential diagnosis includes herpes simplex virus, gonorrhea, *Chlamydia*, trichomoniasis, yeast, and bacterial vaginosis. **Urethritis** causes dysuria that is usually subacute in onset and is associated with a history of discharge and new or multiple sexual partners. Frequency and urgency of urination may be present but are less pronounced than in patients with cystitis, and fever and chills are absent. Urethral discharge with inflammatory cells or initial pyuria in the male is characteristic. The common causes of urethritis include *Neisseria gonorrhoeae*, *Chlamydia*, herpes simplex virus, and trichomoniasis. Appropriate cultures and immunologic tests are indicated. **Urethral injury** associated with sexual intercourse, chemical irritants, or allergy may also cause dysuria. A history of trauma or exposure to irritants and a lack of discharge or pyuria are characteristic.

Management

Antimicrobial Selection. Oral antimicrobial agents for treatment of acute uncomplicated cystitis are listed in Table 12-10.

Nitrofurantoin has maintained an excellent level of activity over 4 decades and is well tolerated, but it is more expensive than TMP-SMX and is considerably less active against aerobic gram-negative rods other than *E. coli*. Furthermore, it is usually prescribed for 5 days and may cause gastrointestinal upset. It is not associated with plasmid-mediated resistance, however, so it is an excellent choice for patients with recent exposure to most other antimicrobial agents. The high in vitro resistance to ampicillin and sulfonamide and the high cost of amoxicillin/clavulanate and the cephalosporins limit their usefulness.

TMP and TMP-SMX are effective and inexpensive agents for empirical therapy, resulting in bacteriologic cure (i.e., eradication of the pathogen from the urine) within 7 days after the start of treatment in approximately 94% of women (Warren et al, 1999). They are recommended in areas where the prevalence of resistance to these drugs among *E. coli* strains causing cystitis is less than 20% (Gupta et al, 2011). The probability of resistant strains can be predicted in part from the history of recent antimicrobial usage. Women who have taken TMP-SMX recently are approximately 16 times as likely to be infected with an isolate resistant to this agent compared with women who have not taken the antimicrobial agent recently. In addition, those who have taken any other antimicrobial agent are more than twice as likely to be infected with a resistant isolate (Brown et al, 2002). With a 30% rate of resistance to TMP-SMX, the bacteriologic eradication rate is predicted to be 80% and the clinical cure rate is predicted to be 85% (Gupta et al, 2001). When used alone, TMP is as efficacious as TMP-SMX and is associated with fewer side effects, presumably because of the absence of the sulfa component (Harbord and Gruneberg, 1981). It can be prescribed to patients who are allergic to sulfa. However, TMP can cause hypersensitivity and rashes that may be erroneously attributed to sulfa (Alonso et al, 1992).

TABLE 12-10 Treatment Regimens for Acute Cystitis

CIRCUMSTANCES	ROUTE	DRUG	DOSAGE (mg)	FREQUENCY PER DOSE	DURATION (DAYS)	COST PER DAY
WOMEN						
Healthy	Oral	Nitrofurantoin macrocrystals	100 mg	bid	5	\$3.24
		TMP-SMX	1 double-strength tablet (160-800 mg)	bid	3	\$0.26
		Trimethoprim	100 mg	bid	3	\$1.32
		Fosfomycin trometamol	3 g	Single dose	—	\$47.99
		Pivmecillinam	400 mg	bid	3-7	Not available in the U.S.
		Ciprofloxacin	250 mg†	bid	3	\$0.50
		Levofloxacin	250 mg†	qd	3	\$5.07
Symptoms for >7 days, recent urinary tract infection, age >65 yr, diabetes, diaphragm use		TMP-SMX or fluoroquinolone	As above	As above	7	As above
Pregnancy	Oral	Amoxicillin	As above	As above	3-7	\$0.68
		Cephalexin	As above	As above		\$1.76
		Nitrofurantoin macrocrystals	As above	As above		As above
		TMP-SMX*	As above	As above		As above
MEN						
Healthy and age <50 yr	Oral	TMP-SMX	As above	As above	7	As above
		Ciprofloxacin	500 mg	bid	7	As above
		Levofloxacin	500 mg	qd	7	As above

*Use of TMP-SMX during the first trimester of pregnancy is cautioned because there is early potential for teratogenicity and late potential for kernicterus after delivery.

†Fluoroquinolones should be reserved for important infections other than acute cystitis except in select situations.

Modified from Schaeffer AJ. Urinary tract infections. In: Gillenwater JY, Grayhack JT, Howards SS, et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211-72; and Gupta K, Hooton TN, Naber KG, et al: International clinical practice guidelines for the treatment of acute uncomplicated cystitis and pyelonephritis in women: a 2010 update by the Infectious Diseases Society of America and the European Society for Microbiology and Infectious Diseases. Clin Infect Dis 2011;52:e103-20.

Fosfomycin trometamol (3 g in a single dose) is an appropriate choice for therapy where it is available because of minimal resistance and propensity for collateral damage, but it may have inferior efficacy compared with standard short-course regimens according to data submitted to the U.S. Food and Drug Administration (FDA) and summarized in the Medical Letter (A-I) ([Fosfomycin for urinary tract infections, 1997; Gupta et al, 2011](#)).

Pivmecillinam (400 mg twice daily for 3 to 7 days) is an appropriate choice for therapy in regions where it is available (availability limited to some European countries; not licensed and/or available for use in North America) because of minimal resistance and propensity for collateral damage, but it may have inferior efficacy compared with other available therapies (A-I) ([Gupta et al, 2011](#)).

The fluoroquinolones offer excellent activity, and are well tolerated. Resistance to the fluoroquinolones remains below 5% in most places ([Fihn et al, 1988](#)); however, it is increasing in certain areas. Twice-daily and once-daily extended-release fluoroquinolones are equally effective ([Henry et al, 2002](#)). They have a high propensity for collateral damage (i.e., ecological adverse effects, such as drug resistance) and should be reserved for important infections other than acute cystitis and thus should be considered alternative antimicrobials for acute cystitis ([Gupta et al, 2011](#)). Their use for uncomplicated cystitis should be limited to patients who are allergic to TMP-SMX, to patients with previous exposure to antimicrobial agents causing bacterial resistance, and to areas where the prevalence of resistance to TMP or TMP-SMX is 20% or greater ([Warren et al, 1999; Hooton et al, 2004](#)).

The effects of an antimicrobial agent on the vaginal flora are also important in recurrence of bacteriuria ([Fihn et al, 1988](#)). The concentrations of TMP and the fluoroquinolones that have been studied in vaginal secretions are high, eradicating *E. coli* but minimally altering normal anaerobic and microaerophilic vaginal flora ([Hooton and Stamm, 1991](#)). Single-dose regimens using these drugs are less effective than multiple-day regimens in this regard ([Fihn et al, 1988](#)), which probably explains why there are more early recurrent infections after single-dose therapy with these drugs. Nitrofurantoin and β -lactam drugs are generally not effective in eliminating *E. coli* from the vagina.

Duration of Therapy. Three-day therapy is the preferred regimen for uncomplicated cystitis in women ([Norrby, 1990; Warren et al, 1999](#)). In an excellent review of more than 300 separate clinical trials of single-dose, 3-day, or 7-day treatment with TMP, TMP-SMX, fluoroquinolones, and β -lactam antimicrobial therapies, it was concluded that, irrespective of the antimicrobial used, 3-day therapy is more effective than single-dose therapy. Three-day therapy with TMP-SMX, TMP, amoxicillin, or cefaclor has been associated with cure rates similar to longer courses of therapy and an incidence of adverse effects about as low as that seen with single-dose therapy and lower than seen with longer courses of therapy ([Charlton et al, 1976; Kunin, 1985; McCue, 1986; Warren et al, 1999](#)). Because 7-day therapy often causes more adverse effects, it is recommended only for women with symptoms of 1 week or more, men, and individuals with possible complicating factors. Other options include nitrofurantoin, perhaps as 7-day therapy, and fosfomycin single-dose therapy; each of these requires further study. β -Lactams as a

group are less effective in treatment of cystitis than TMP, TMP-SMX, and the fluoroquinolones.

Seven-day therapy is the preferred regimen in uncomplicated cystitis in men.

Cost of Therapy. The cost of treating a UTI involves not only the initial evaluation and cost of the drug but also what occurs subsequently. The most important prediction of high cost-effectiveness is high efficacy against the most common urinary pathogen, *E. coli*. The lower the effectiveness against this bacterium, the greater the number of revisits, cases of progression to pyelonephritis, and follow-up costs. Antimicrobial cost is a poor prediction of cost-effectiveness, as illustrated by the finding that the most expensive and least expensive drugs, the fluoroquinolones and TMP-SMX, are approximately equally cost-effective (Rosenberg, 1999). Both of these drugs are more cost-effective than nitrofurantoin and amoxicillin.

Follow-Up

Approximately 90% of women are asymptomatic within 72 hours after initiating antimicrobial therapy (Fihn et al, 1988). A follow-up visit or culture is not required in young women who are asymptomatic after therapy. A follow-up visit, urinalysis, and urine culture are recommended in older women or those with potential risk factors and in men. Urologic evaluation is unnecessary in women and is usually unnecessary in young men who respond to therapy (Lipsky, 1989; Abarbanel et al, 2003). However, UTIs in most men should be considered complicated until proven otherwise. Andrews and associates (2002) showed that approximately 50% of men with UTIs have a significant abnormality. Furthermore, if a patient does not respond to therapy, appropriate microbiologic urologic evaluations should be undertaken for the causes of unresolved and complicated UTIs.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria is a microbiologic diagnosis based on the isolation of a specified quantitative count of bacteria in a properly collected specimen of urine from a patient who is without symptoms or signs referable to UTI. In healthy individuals, the absence of symptoms is clear cut, but, for example, in catheterized or neurologically compromised patients, it may be difficult to discern whether the UTI is truly asymptomatic. Kass (1962) originally proposed that for asymptomatic women two consecutive voided urine specimens with isolation of the same bacterial strain in quantitative counts of 10^5 cfu/mL is consistent with asymptomatic bacteriuria. In men, a single clean-catch voided specimen with similar counts is adequate. A single catheterized urine specimen with a solitary isolate with a quantitative count of 10^2 cfu/mL identifies bacteriuria in women or men (Nicolle et al, 2005). The prevalence of pyuria with asymptomatic bacteriuria ranges from approximately 30% in young women (Hooton et al, 2000) to 100% in catheterized patients. In addition, many coexisting factors, such as stones, can incite inflammation in these patients, and therefore the presence or absence of pyuria is not sufficient to diagnose bacteriuria nor does it differentiate symptomatic from asymptomatic patients or provide indication for antimicrobial treatment (Nicolle et al, 2005).

The prevalence of asymptomatic bacteriuria varies widely and depends on the age, sex, and the presence of other genitourinary abnormalities (Table 12-11). *E. coli* is the most common isolate among patients with bacteriuria, and it contains fewer virulence characteristics than isolates from patients with symptomatic infections (Svanborg and Godaly, 1997). Other Enterobacteriaceae (e.g., *P. mirabilis*) and gram-positive uropathogens, including group B streptococci and coagulase-negative staphylococci, become more prevalent in concert with increased underlying abnormalities. For patients who are institutionalized and/or with indwelling urologic devices, *P. aeruginosa*, *Proteus*, and other highly resistant organisms are more prevalent.

TABLE 12-11 Prevalence of Asymptomatic Bacteriuria in Selected Populations

POPULATION	PREVALENCE (%)	REFERENCE
Healthy, premenopausal women	1.0-5.0	Nicolle, 2003
Pregnant women	1.9-9.5	Nicolle, 2003
Postmenopausal women aged 50-70 years	2.8-8.6	Nicolle, 2003
Diabetic patients		
Women	9.0-27	Zhanel, 1991
Men	0.7-11	Zhanel, 1991
Elderly persons in the community		
Women	10.8-16	Nicolle, 2003
Men	3.6-19	Nicolle, 2003
Elderly persons in a long-term care facility		
Women	25-50	Nicolle, 1997
Men	14-50	Nicolle, 1997
Patients with spinal cord injuries		
Intermittent catheter use	23-89	Bakke and Digranes, 1991
Sphincterotomy and condom catheter in place	57	Waites et al, 1993b
Patients undergoing hemodialysis	28	Chaudhry, 1993
Patients with indwelling catheter use		
Short-term	9-23	Stamm, 1991
Long-term	100	Warren, 1982

From Nicolle LE, Bradley S, Colgan R, et al. Infectious Diseases Society of America guidelines for the diagnosis and treatment of asymptomatic bacteriuria in adults. Clin Infect Dis 2005;40:643-54.

Management of asymptomatic bacteriuria is determined by the population and their risk for adverse outcome, which can be prevented with antimicrobial treatment of asymptomatic bacteriuria (Nicolle et al, 2005) (Table 12-12). These recommendations are based on the observation that in adult populations asymptomatic bacteriuria has not been shown to be harmful. Furthermore, although persons with bacteriuria are at increased risk of symptomatic urinary tract infections, treatment of asymptomatic bacteriuria does not decrease the frequency of symptomatic infections or improve other outcomes. Thus, in populations other than those for whom treatment has been documented to be beneficial (e.g., pregnant women and patients undergoing urologic interventions), screening for or treatment of asymptomatic bacteriuria is not appropriate and should be discouraged (Nicolle et al, 2005).

Complicated Cystitis

Complicated UTIs are those that occur in a patient with a compromised urinary tract or that are caused by a very resistant pathogen (Box 12-7). These complicating factors may be readily apparent

from the severity of the presenting illness or the past medical history. However, they may not be obvious at first and may only become evident from subsequent failure of the patient to respond to appropriate therapy (see later discussion on [unresolved](#) or [recurrent UTIs](#)).

The clinical spectrum ranges from mild cystitis to life-threatening kidney infections and urosepsis (kidney infections and urosepsis are discussed subsequently). These infections can be caused by a broad range of bacteria with resistance to multiple

antimicrobial agents. Therefore urine cultures are mandatory to identify the bacteria and its antimicrobial susceptibility.

Because of the wide range of host conditions and pathogens and a lack of adequate controlled trials, guidelines for empirical therapy are limited. For patients with mild to moderate illness who can be treated as an outpatient with oral therapy, the fluoroquinolones provide a broad spectrum of activity with excellent urine and tissue levels and safety. If the susceptibility pattern of the pathogen is known, TMP-SMX may be effective ([Table 12-13](#)).

For patients requiring hospitalization, IV antimicrobials should be administered based on the susceptibility patterns of the known uropathogens at that institution.

Because therapy will be compromised without addressing complicating factors, every effort should be made to correct any underlying urinary tract abnormalities and treat host factors that exacerbate the infection.

Therapy is usually continued for 10 to 14 days and switched from parenteral to oral therapy when the patient is afebrile and clinically stable. Repeat urine cultures should be performed if the patient fails to respond to therapy.

TABLE 12-12 Screening for and Treatment of Asymptomatic Bacteriuria

Premenopausal nonpregnant women	Not recommended
Pregnant women	Recommended
Diabetic women	Not recommended
Older persons residing in the community	Not recommended
Elderly institutionalized subjects	Not recommended
Subjects with spinal cord injuries	Not recommended
Patients with indwelling urethral catheters	Not recommended
<i>Note:</i> Antimicrobial treatment of asymptomatic women with catheter-associated bacteriuria that persists 48 hours after catheter removal may be considered.	
Urologic interventions	Recommended
Immunocompromised patients and transplant patients	Not recommended

BOX 12-7 Complicating Host Factors

Functional/structural abnormalities of urinary tract
Recent urinary tract instrumentation
Recent antimicrobial agent use
Diabetes mellitus
Immunosuppression
Pregnancy
Hospital-acquired infection

Unresolved UTIs

Clinical Presentation

Unresolved infection indicates that initial therapy has been inadequate in eliminating symptoms and/or bacterial growth in the urinary tract. If the symptoms of UTI do not resolve by the end of treatment or if symptoms recur shortly after therapy, urinalysis and urine culture with susceptibility testing should be obtained. If the patient's symptoms are significant, empirical therapy with a fluoroquinolone is appropriate, pending results of the culture and susceptibility testing.

The causes of unresolved bacteriuria during antimicrobial therapy are shown in [Box 12-8](#). Most commonly, the bacteria are resistant to the antimicrobial agent selected to treat the infection. Typically, the patient has received the antimicrobial therapy in the recent past and developed bowel colonization with resistant bacteria. β -lactams, tetracycline, and sulfonamides are notorious for causing plasmid-mediated R factors that simultaneously carry resistance to multiple antimicrobial agents. The second most common cause is development of resistance in a previously susceptible population of bacteria during the course of treatment of UTIs. This problem occurs in approximately 5% of the patients receiving antimicrobial therapy. It is easy to recognize clinically because the culture on therapy shows that the previous susceptible population has been replaced by resistant bacteria of the same species. It can be shown that resistant organisms were actually present

TABLE 12-13 Treatment of Complicated Urinary Tract Infections

COMMON PATHOGENS	MITIGATING CIRCUMSTANCES	RECOMMENDED EMPIRICAL TREATMENT
<i>E. coli</i> , <i>Proteus</i> species, <i>Klebsiella</i> species, <i>Pseudomonas</i> species,	Mild-to-moderate illness, no nausea or vomiting—outpatient therapy	Oral* ciprofloxacin or ofloxacin for 10–14 days
<i>Serratia</i> species, enterococci, staphylococci	Severe illness or possible urosepsis—hospitalization required	Parenteral† ampicillin and gentamicin, ciprofloxacin, levofloxacin, ceftriaxone, aztreonam, ticarcillin-clavulanate or imipenem-cilastatin until fever gone; then oral* trimethoprim-sulfamethoxazole, norfloxacin, ciprofloxacin, or levofloxacin for 14–21 days

*Oral regimens for pyelonephritis and complicated urinary tract infection: trimethoprim-sulfamethoxazole, 160 and 800 mg q12h; ciprofloxacin, 500 mg q12h; levofloxacin, 500 mg/day.

†Parenteral regimens: ciprofloxacin, 400 mg q12h; levofloxacin, 250 mg/day; gentamicin, 1 mg/kg q8h; ceftriaxone, 1 to 2 g/day; ampicillin, 1 g q6h; imipenem-cilastatin, 250 to 500 mg q6–8h; ticarcillin-clavulanate, 3.1 g q6h; and aztreonam, 1 g q8–12h.

BOX 12-8 Causes of Unresolved Bacteriuria, in Descending Order of Importance

Bacterial resistance to the drug selected for treatment
 Development of resistance from initially susceptible bacteria
 Bacteriuria caused by two different bacterial species with mutually exclusive susceptibilities
 Rapid reinfection with a new, resistant species during initial therapy for the original susceptible organism
 Azotemia
 Papillary necrosis from analgesic abuse
 Giant staghorn calculi in which the “critical mass” of susceptible bacteria is too great for antimicrobial inhibition
 Self-inflicted infections or deception in taking antimicrobial drugs (a variant of Munchausen syndrome)

before contact with the initial antimicrobial agent, but they were present in such low numbers that it was impossible to detect by *in vitro* susceptibility studies before therapy. When the antimicrobial concentration in the urine is insufficient to kill all the bacteria present, the more resistant forms will emerge. This characteristically is seen in patients who are underdosed or who are poorly compliant and hence have inadequate dose regimens. The third cause is the presence of an unsuspected, second pathogen that was present initially and is resistant to the antimicrobial therapy chosen. Treatment of the dominant organism unmasks the presence of the second strain. The fourth cause is rapid reintroduction of a new resistant species while the patient is undergoing initial therapy. Rapid reinfection that mimics unresolved bacteriuria should alert the clinician to the possibility of an enterovesical fistula.

If the culture obtained on therapy shows that the initial species is still present and susceptible to the antimicrobial chosen to treat the infection, the unresolved infection must be caused by either inability to deliver an adequate concentration of antimicrobial agents into the urinary tract or an excessive number of bacteria that “override” the antimicrobial activity. In patients with azotemia, a determination of urinary antimicrobial concentrations usually shows that the level of the drug is below the minimal inhibitory concentration of the infecting organism.

In patients with papillary necrosis, severe defects in the medullary concentrating ability dilute the antimicrobial agent. A large mass of bacteria within the urinary tract is most commonly associated with a giant staghorn calculus. Even though adequate urinary levels of bactericidal drugs are present, the concentration is inadequate to sterilize the urine. This occurs because even susceptible bacteria cannot be inhibited once they reach a certain critical density, particularly if attached to a foreign body.

The last cause of unresolved bacteriuria occurs in those patients who have variants of Munchausen syndrome. These patients secretly inoculate their bladders with uropathogens or omit their oral antimicrobial agents while steadfastly asserting that they never miss a dose. The patient with Munchausen syndrome presents with an inconsistent clinical history and invariably a normal urinary tract on urologic imaging. Careful bacteriologic observations usually indicate the implausibility of the clinical picture.

Laboratory Diagnosis

Urinalysis and urine culture are mandatory to determine the cause of unresolved bacteriuria. The first four causes that are associated with resistant bacteria require no further evaluation. However, if reculture shows that the bacteria are sensitive to the antimicrobial agent the patient is taking, renal function and radiologic evaluation should be performed to identify renal or urinary tract abnormalities.

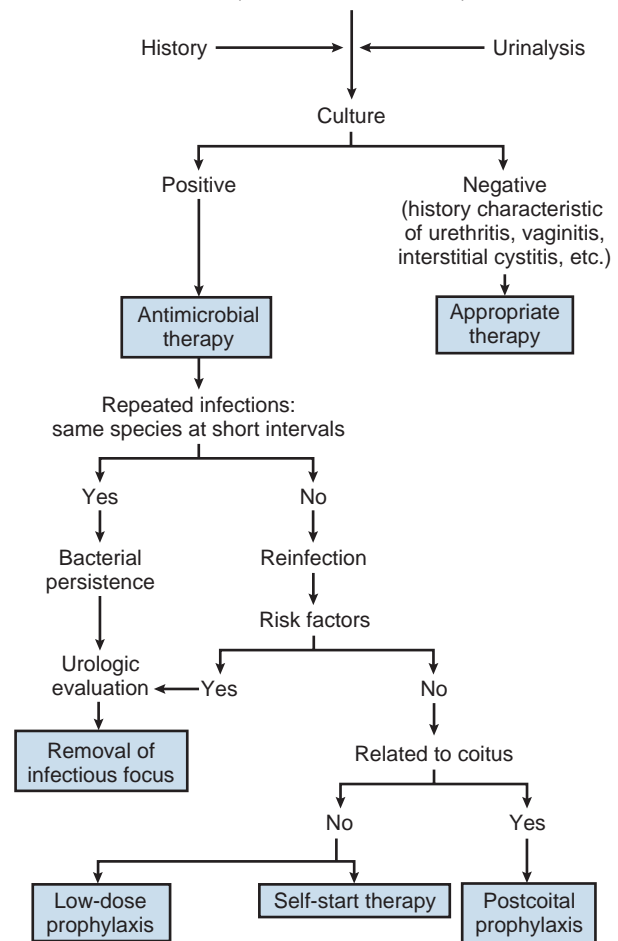

Symptoms and Signs of Recurrent Urinary Tract Infection (No Fever or Flank Pain)

Figure 12-14. Management of recurrent urinary tract infection.

Management

Initial empirical antimicrobial selection should be based on the assumption that the bacteria are resistant. Therefore an antimicrobial agent different from the original agent should be selected. Fluoroquinolones offer excellent coverage in most cases and should be given for 7 days. When the bacterial susceptibilities are available, adjustments can be made if necessary. Urine cultures should be performed during and 7 days after therapy to ensure microbiologic efficacy.

Recurrent UTIs

Recurrent UTIs are caused by either reemergence of bacteria from a site within the urinary tract (bacterial persistence) or new infections from bacteria outside the urinary tract (reinfection). Clinical identification of these two types of recurrence is based on the pattern of recurrent infections (Fig. 12-14). Bacterial persistence must be caused by the same organism in each instance, and infections that occur at close intervals are characteristic. Conversely, reinfections usually occur at varying and sometimes long intervals and often are caused by different species. The distinction between bacterial persistence and reinfection is important in management because patients with bacterial persistence can usually be cured of the recurrent infections by identification and surgical removal or correction of the focus of infection. Conversely, women with reinfection usually do not have an alterable urologic abnormality and require long-term medical management. Reinfections in men are uncommon and may be associated

with an underlying abnormality, such as urethral stricture; therefore, at a minimum, endoscopic evaluation is indicated.

Bacterial Persistence

Once the bacteriuria has resolved (i.e., the urine shows no growth for several days after the antimicrobial agent has been stopped), recurrence with the same organism can arise from a site *within* the urinary tract that was excluded from the high urine concentrations of the antimicrobial agent. The 12 correctable urologic abnormalities that cause bacteria to persist within the urinary tract between episodes of recurrent bacteriuria are listed in **Box 12-4**. The relationship of these abnormalities to bacterial persistence, as well as the documentation that surgical excision removes the infection as a source of recurrent bacteriuria, is presented elsewhere in detail (**Stamey, 1980**). Once the urologist recognizes that the cause of the patient's recurrent bacteriuria is bacterial persistence, **Box 12-4** should serve as a checklist for known, correctable causes. Some of the causes are subtle, and many require cystoscopic localization of the infection with ureteral catheters to accurately define the focus of bacterial persistence.

Although patients with bacterial persistence are relatively uncommon, their identification is important because they represent the only surgically curable cause of recurrent UTIs. A systematic radiologic and endoscopic evaluation of the urinary tract is mandatory. CT and cystoscopy provide the initial screening. Retrograde urography may be required in selected patients to delineate abnormalities, such as diverticulum or nonrefluxing ureteral stump.

Urea-Splitting Bacteria That Cause Struvite Renal Stones. The infection that ultimately leads to an infection stone commonly begins inconspicuously as inadequately treated cystitis. Most patients with *P. mirabilis* cystitis do not form struvite stones. But struvite stones form in those patients who have a protracted infection with *P. mirabilis*, an infection that is often asymptomatic or minimally symptomatic. *P. mirabilis* causes intense alkalization of the urine with precipitation of calcium, magnesium, ammonium, and phosphate salts and the subsequent formation of branched struvite renal stones. Bacteriuria in most of these patients with struvite stones recurs almost immediately on stopping antimicrobial therapy, usually within 5 to 7 days. The bacteriologic consequences are substantial because the bacteria persist inside these struvite stones even when the urine shows no growth. Indeed, struvite infection stones, together with the occasional oxalate or apatite stone that becomes secondarily colonized, constitute the major cause of bacterial persistence in women in the absence of azotemia.

Underlying urinary tract abnormalities are not a prerequisite for this type of infection. However, patients with indwelling catheters, urinary diversions, or other urinary tract abnormalities are particularly susceptible to these infections. Urea-splitting organisms, such as *P. mirabilis*, cause infection stones that are relatively radiolucent. If such a stone is suspected, plain film tomograms or CT scans without contrast medium enhancement should be obtained (**Greenberg et al, 1982**). Medical management with continued suppressive antimicrobial therapy and acidification temporarily relieves symptoms and retards deterioration of renal function in some patients. Complete removal of the calculus is generally required for bacteriologic cure and to prevent renal damage caused by obstruction (**Silverman and Stamey, 1983**). Percutaneous nephrolithotomy and extracorporeal shockwave lithotripsy are now the preferred treatment for most renal and upper ureteral calculi.

When extracorporeal shockwave lithotripsy is used to fragment infection stones, the patient should be maintained on appropriate antimicrobial therapy until the fragments pass. Occasionally, long-term antimicrobial therapy can result in eradication of bacteriuria even if some fragments persist after lithotripsy, presumably because the shockwaves have rendered the entrapped bacteria more susceptible to antimicrobial therapy (**Michaels et al, 1988**). If percutaneous or open surgery is used, all the residual particles of struvite stones must be removed at surgery to prevent recurrent bacteriuria from bacterial persistence in the calculus.

Rocha and Santos (1969) have shown that soaking these stones in iodine and alcohol for 6 hours will not kill the bacteria within the interior of the stone. The importance of recognizing this fact is twofold: (1) The bacteria cannot be killed by antimicrobial therapy, even though the urine may show no growth for months or even years (**Shortliffe et al, 1984**), and (2) any fragments left behind at the time of surgical removal leave residual bacteria within the interstices of the stone; these bacteria ensure recurrence of the staghorn calculus with its attendant morbidity.

If fragments remain after surgery, a small, multihole polyethylene catheter should be left for postoperative irrigation with Renacidin or Suby G solution (**Silverman and Stamey, 1983**). Follow-up radiographs are essential to ensure that all the stone fragments are removed, and cultures must demonstrate that the urease-splitting bacteria are eradicated.

Most of the other congenital or acquired abnormalities listed in **Box 12-4** require surgical removal for eradication of the source of bacterial persistence. Chronic bacterial prostatitis is treated initially with long-term antimicrobial therapy and, in select cases, by radical transurethral resection (**Meares, 1978**).

In patients in whom the focus of infection cannot be eradicated, long-term, low-dose antimicrobial suppression is necessary to prevent symptoms of infection. The antimicrobial drugs used for low-dose prophylaxis will also be effective for bacterial suppression if the persistent strain is susceptible. These include nitrofurantoin, TMP-SMX, cephalexin, and the fluoroquinolones.

Reinfections

Patients with recurrent infections caused by different species or occurring at long intervals almost invariably have reinfections. These reinfections most often occur in women and girls and are associated with ascending colonization from the bowel flora. Reinfections in men are often associated with a urinary tract abnormality. The possibility of a vesicoenteric or vesicovaginal fistula should be considered when the patient has any history of pneumonia, fecaluria, diverticulitis, obstipation, previous pelvic surgery, or radiation therapy. Evaluation of the patient with presumed reinfections must be individualized.

Failure to recognize and correct abnormalities that reduce formation, transmission, and elimination of urine by the urinary tract increases the incidence of reinfection in susceptible patients and reduces the effectiveness of antimicrobial therapy. Abnormalities should be corrected and urinary tract function restored by medical, pharmacologic, or surgical management. A thorough urologic evaluation is essential in all men and in women with evidence of upper tract infections (fevers, chills, flank pain, hemorrhagic cystitis, or other risk factors, such as history of unexplained hematuria, obstructive symptoms, neurogenic bladder dysfunction, renal calculi, fistula, analgesic abuse, or severe disease such as diabetes mellitus). In women, diaphragm-spermicide use has been associated with an increased risk of UTI and vaginal colonization with *E. coli* (**Hooton et al, 1991b**). Spermicides containing the active ingredient nonoxynol-9 may provide a selective advantage in colonizing the vagina, perhaps by a reduction in vaginal lactobacilli and through enhancement of adherence of *E. coli* to epithelial cells (**Hooton et al, 1991a; Gupta et al, 2000**). Thus spermicides should be discontinued in women with recurrent UTI, and other forms of contraception should be used.

Postmenopausal women have frequent reinfections (**Hooton and Stamm, 1991; Raz and Stamm, 1993**). These infections are sometimes attributable to residual urine after voiding, which is often associated with bladder or uterine prolapse. In addition, the lack of estrogen causes marked changes in the vaginal microflora, including a loss of lactobacilli and increased colonization by *E. coli* (**Raz and Stamm, 1993**). Estrogen replacement frequently restores the normal vaginal environment, allows recolonization with lactobacilli, and thus eliminates bacterial uropathogenic colonization. A reduced incidence of UTIs has been documented with this approach (**Raz and Stamm, 1993**).

Urinary tract imaging will demonstrate the anatomy of the urinary tract and provide reasonable assessment of its functional status. In healthy women, upper tract abnormalities associated with reinfections are very rare; therefore routine urologic imaging is not indicated. Cystoscopy should be performed in men or women who have frequent reinfections and symptoms suggestive of obstruction, bladder dysfunction, and fistula. If the patient has residual urine that is judged to be significant (e.g., 100 mL) and due to a narrowing of the urethra, a single dilation of the urethra to improve bladder emptying would appear appropriate. There is little evidence, however, that repeated urethral dilation is indicated in the routine management of most women.

Antimicrobial management in women who have had two or more symptomatic UTIs over a 6-month period or three or more episodes within a 12-month period involves one of three regimens: low-dose continuous prophylaxis, self-start intermittent therapy, or postintercourse prophylaxis.

Low-Dose Continuous Prophylaxis

Biologic Basis of Successful Prophylaxis: Antimicrobial Effect on Bowel and Vaginal Bacterial Flora. The success of prophylaxis depends, in large part, on the effect an antimicrobial agent has on the introital and bowel reservoirs of pathogenic bacteria. Antimicrobial agents that eliminate pathogenic bacteria from

these sites and/or do not cause bacterial resistance at the sites can be effective for antimicrobial prophylaxis of UTIs (Table 12-14).

Winberg and his colleagues were among the first to emphasize that oral antimicrobial therapy causes resistant strains in the bowel flora and subsequent resistant UTIs (Lincoln et al. 1970; Winberg et al. 1973). The increase in resistant strains of *E. coli* is well documented, as is the proliferation of other Enterobacteriaceae species, *Candida albicans*, enterococci, and other pathogenic bacteria in the bowel and vaginal flora that accompanies even short-term, full-dose oral administration of tetracyclines, ampicillin, sulfonamides, amoxicillin, and cephalexin (Sharp, 1954; Daikos et al. 1968; Hinton, 1970; Lincoln et al. 1970; Datta et al. 1971; Gruneberg et al. 1973; Winberg et al. 1973; Toivanen et al. 1976; Ronald et al. 1977; Preiksaitis et al. 1981). These ecologic changes may interfere with antimicrobial prophylaxis in the urinary tract and must be considered in the choice of prophylactic agents.

Effective Drugs. The oral antimicrobial agents with minimal adverse effects on the bowel and vaginal flora are TMP-SMX or TMP alone, nitrofurantoin, cephalexin (in minimal dosage), and the fluoroquinolones.

TMP-SMX eradicates gram-negative aerobic flora from the bowel and vaginal fluid. Vaginal fluid measurements of TMP and

TABLE 12-14 Low-Dose Prophylaxis for Recurrent Urinary Tract Infections in Women

INVESTIGATORS	REGIMEN	INFECTIONS PER PATIENT-YEAR
Bailey et al (1971)	Nitrofurantoin, 50 or 100 mg daily	0.09
	Nitrofurantoin, 50 mg daily	0.19
	Placebo	2.1
Harding and Ronald (1974)	Sulfamethoxazole, 500 mg daily	2.5
	TMP-SMX, 40 and 200 mg daily	0.1
	Methenamine mandelate, 2 g daily, plus ascorbic acid, 2 g	1.6
Kasanen et al (1974)	Nitrofurantoin, 50 mg daily	0.32
	Methenamine hippurate, 1 g daily	0.39
	Trimethoprim, 100 mg daily	0.13
	TMP-SMX, 80 and 400 mg daily	0.19
Gower (1975)	Cephalexin, 125 mg daily	0.10
Stamey et al (1977)	TMP-SMX, 40 and 200 mg daily	0.00
	Nitrofurantoin macrocrystals, 100 mg daily	0.74
Harding et al (1979)	TMP-SMX, 40 and 200 mg three times weekly	0.1
Stamm et al (1980)	TMP-SMX, 40 and 200 mg daily	0.15
	Trimethoprim, 100 mg daily	0.00
	Nitrofurantoin macrocrystals, 100 mg daily	0.14
	Placebo	2.8
Brumfitt et al (1981)	Nitrofurantoin, 50 mg twice daily	0.19
	Methenamine hippurate, 1 g twice daily	0.57
Harding et al (1982)	TMP-SMX, 40 and 200 mg three times weekly	0.14
Brumfitt et al (1983)	Trimethoprim, 100 mg daily	1.53
	Methenamine hippurate, 1 g daily	1.38
	Povidone-iodine wash, twice daily	1.79
Wong et al (1985)	TMP-SMX, 40 and 200 mg daily	0.2
	Self-administered cotrimoxazole, 4 × 80 and 400 mg	2.2
Martinez et al (1985)	Cephalexin, 250 mg daily	0.18
Brumfitt et al (1985)	Trimethoprim, 100 mg daily	1.00
	Nitrofurantoin macrocrystals, 100 mg daily	0.16
Nicolle et al (1989)	Nitrofurantoin, 200 mg daily	0.00

TMP-SMX, trimethoprim-sulfamethoxazole.

Modified from Nicolle LE, Ronald AR. Recurrent urinary tract infection in adult women: diagnosis and treatment. *Infect Dis Clin North Am* 1987;1:793–806.

SMX in patients showed that TMP infused across the noninflamed vaginal wall and produced concentrations that exceeded serum levels (Stamey and Condy, 1975); SMX was undetectable in vaginal fluid. These observations on diffusion and concentration of TMP and vaginal fluid and on the effects of TMP-SMX in clearing Enterobacteriaceae from the rectal and vaginal flora clearly indicate why TMP-SMX is such a powerful prophylactic agent for the prevention of reinfections in the female. These important biologic effects occur in addition to the bactericidal levels of TMP-SMX that are present in the urine during nightly prophylaxis.

Kasanen and his colleagues (1978) in Finland studied the bowel flora in volunteers and patients who took 100 mg of TMP per day for periods of 3 weeks to 36 months; 4 of 20 patients treated for long periods developed coliforms resistant to TMP ($>8 \mu\text{g/mL}$). Svensson and his associates (1982) gave 100 mg of TMP once daily for 6 months to 26 patients with recurrent UTIs. The infection recurrence rate before prophylaxis was 26 per 100 months compared with 3.3 recurrences per 100 months during prophylaxis ($P = .001$). The postprophylactic infection rate returned to 23 recurrences per 100 months. It is important to note that all *E. coli* UTIs after prophylaxis were sensitive to TMP, the number of rectal Enterobacteriaceae was markedly reduced during prophylaxis, and, although a 10% incidence of TMP-resistant organisms from rectal swabs was observed less than 1 month into prophylaxis, there was no significant further accumulation of resistant bacteria.

These studies on TMP alone suggest that it should be as effective as TMP-SMX for prophylactic prevention of recurrent UTIs. Stamm and coworkers (1980a) noted only one resistant strain of *E. coli* in 316 rectal, urethral, and vaginal isolates from 15 patients receiving 100 mg of TMP and 15 others receiving 40 mg of TMP with 200 mg of SMX nightly for 6 months; their unbelievably low recovery of TMP-resistant *E. coli* was due to their method of sampling, which did not include streaking cultures from these colonization sites directly onto media containing TMP.

These studies on TMP-SMX and TMP prophylactic therapy usually have been limited to 6 months to test continuing susceptibility in patients with reinfections. Two studies (Pearson et al, 1979; Harding et al, 1982), however, continued TMP-SMX prophylaxis from 2 to 5 years without showing any increase in "breakthrough" infections or any increase in TMP-resistant recurrent infections. Indeed, in the 15 patients treated for 2 years with one-half tablet of TMP-SMX thrice weekly (Harding et al, 1982), 100 of 116 cultures from the periurethral area (91%) and 60 of 97 cultures from the anal canal (68%) showed no aerobic gram-negative bacilli at these colonization sites.

Nitrofurantoin, which does not alter the bowel flora, is present for brief periods at high concentrations in the urine and leads to repeated elimination of bacteria from the urine, presumably interfering with bacterial initiation of infection. Because of either its complete absorption in the upper intestinal tract or its degradation and inactivation in the intestinal tract, it produces minimal effects on bowel flora (Stamey et al, 1977). Unlike the situation in prophylaxis with TMP-SMX that eliminates colonization, in prophylaxis with nitrofurantoin colonization of the vaginal introitus with Enterobacteriaceae continues throughout therapy. The bacteria colonizing the vagina nearly always remain susceptible because of the lack of bacterial resistance in the bowel flora. Patients on long-term therapy should be monitored for adverse reactions, (e.g., pulmonary fibrosis). The risk of an adverse reaction increases with age, with the greatest number occurring in patients older than 50 years. If a patient develops a chronic cough, the drug should be discontinued and a chest radiograph obtained.

Fairley and his associates (1974) first reported on the prophylactic efficacy of 500 mg of cephalexin per day in preventing recurrent infections during a 6-month period of observation. Of the 22 patients, 17 remained free of infection, an impressive record because several patients had papillary necrosis, chronic pyelonephritis, and even renal calculi. Gower (1975) treated 25 women with 125 mg of cephalexin nightly for 6 to 12 months and found only 1 infection, whereas 13 of 25 women receiving a placebo had infection.

Martinez and coworkers (1985) studied the effect on the vaginal and rectal flora of 250 mg of cephalexin nightly for 6 months in 23 patients with reinfections of the urinary tract. Throughout prophylaxis, 22 of the 23 patients maintained a sterile urine; a single patient developed two enterococcal UTIs, both of which responded to nitrofurantoin. No change was detected in the rectal or vaginal carriage of Enterobacteriaceae. More importantly, not a single resistant strain of *E. coli* was detected in 154 cultures obtained at monthly intervals during cephalexin therapy. These results are in contrast to those of Preiksaitis and colleagues (1981), who found rectal Enterobacteriaceae resistance in 38% of patients when cephalexin was administered at a dose of 500 mg four times daily for 14 days. **Cephalexin at 250 mg or less nightly is an excellent prophylactic agent because bowel flora resistance does not develop at this low dosage.**

With short-course fluoroquinolone therapy (Hooton et al, 1989), eradication of Enterobacteriaceae from the bowel and vaginal (Nord, 1988; Tartaglione et al, 1988) flora has been documented—observations that have been exploited in the use of these agents for prophylaxis. More recently, Nicolle and coworkers (1989) documented the prophylactic efficacy of norfloxacin for the prevention of recurrent UTIs in women. Of 11 women who completed 1 year of prophylaxis (200 mg orally), all remained free of infection. By comparison, the majority of individuals receiving placebos developed UTIs. The drug was well tolerated. In addition to preventing symptomatic UTIs, norfloxacin virtually eradicated periurethral and bowel colonization with aerobic gram-negative organisms. A larger study by Raz and Boger (1991) confirmed these results.

Because the fluoroquinolones are expensive and can be used only in nonpregnant women, we favor their use only when antimicrobial resistance or patient intolerance to TMP-SMX, TMP, nitrofurantoin, or cephalexin occurs. Further studies are required to determine the minimal effective regimen and efficacy of the fluoroquinolones for prophylaxis of recurrent UTIs in women.

Efficacy of Prophylaxis. Low-dose continuous prophylaxis is indicated when the urine culture shows no growth (usually when a patient has completed antimicrobial therapy). Nightly therapy is then begun with one of the following drugs: (1) nitrofurantoin, 50 to 100 mg half-strength (HS) (Stamey et al, 1977); (2) TMP-SMX, 40 to 200 mg (Stamm et al, 1982a); (3) TMP, 50 mg (Stamm et al, 1982a); or (4) cephalexin (Keflex), 250 mg (Martinez et al, 1985). Prophylactic therapy has been repeatedly documented as being effective in the management of women with recurrent UTIs, with recurrences decreased by 95% when compared with placebo or with the patients' prior experiences as controls. These reported results of prophylaxis, together with agents and doses, have been summarized by Nicolle and Ronald (1987) (see Table 12-14). These studies consistently show a remarkable reduction in the reinfection rate from 2.0 to 3.0 per patient-year to 0.1 to 0.4 per patient-year with the use of prophylaxis. Urinary antiseptics, such as methenamine mandelate or hippurate, have resulted in some decrease in recurrences, but they are not as effective as antimicrobial agents.

Every-other-night therapy is also effective and is probably practiced by most patients. When breakthrough infections occur, they are not necessarily accompanied by symptoms; therefore we advocate monitoring for infections every 1 to 3 months, even in asymptomatic patients. Breakthrough infections usually respond to full-dose therapy with the drug used for prophylaxis. However, cultures and susceptibility tests may indicate that another drug is indicated. After the infection is cured, prophylaxis may be reinstituted. Low-dose prophylaxis is usually discontinued after about 6 months, and the patient is monitored for reinfection. Approximately 30% of women will have spontaneous remissions that last up to 6 months (Kraft and Stamey, 1977). Unfortunately, many of the remissions are followed by reinfections, and low-dose prophylaxis must be reinstituted. At this point, many patients prefer an alternative form of management.

Self-Start Intermittent Therapy. With self-start intermittent therapy, the patient is given a dip slide device to culture the urine and is instructed to perform a urine culture when symptoms of UTI occur (Schaeffer and Stuppy, 1999; Blom et al, 2002). The patient is also provided a 3-day course of empirical, full-dose antimicrobial therapy to be started immediately after performing the culture. It is important that the antimicrobial agent selected for self-start therapy have a broad spectrum of activity and achieve high urinary levels to minimize development of resistant mutants. In addition, there should be minimal or no side effects on the bowel flora. Fluoroquinolones are ideal for self-start therapy because they have a spectrum of activity broader than any of the other oral agents and are superior to many parenteral antimicrobials, including aminoglycosides. Nitrofurantoin and TMP-SMX are acceptable alternatives, although they are somewhat less effective. Antimicrobial agents such as tetracycline, ampicillin, SMX, and cephalexin in full doses should be avoided because they can give rise to resistant bacteria (Wong et al, 1985).

The culture is brought to the office as soon as possible. If the culture is positive and the patient is asymptomatic, a culture is performed 7 to 10 days after therapy to determine efficacy. In most cases, the therapy is limited to two inexpensive dip slide cultures and a short course of antimicrobial therapy. If the patient has symptoms that do not respond to initial antimicrobial therapy, a repeat culture and susceptibility testing of the initial culture specimen are performed and therapy adjusted accordingly. If symptoms of infection are not associated with positive cultures, urologic evaluation should be performed to rule out other causes of irritative bladder symptoms, including carcinoma in situ, interstitial cystitis, and neurogenic bladder dysfunction. Our experience with this technique has been very favorable and is particularly attractive to patients who have less frequent infections and are willing to play an active role in their diagnosis and management.

Postintercourse Prophylaxis. Antimicrobial management through postintercourse prophylaxis is based on research establishing that sexual intercourse can be an important risk factor for acute cystitis in women (Nicolle et al, 1982). Diaphragm users have a significantly greater risk of UTI than do women who use other contraceptive methods (Fihn et al, 1985). Postintercourse therapy with antimicrobial agents, such as nitrofurantoin, cephalexin, TMP-SMX, or a fluoroquinolone taken as a single dose, will effectively reduce the incidence of reinfection (Pfau et al, 1983; Melekos et al, 1997).

Other Strategies. Cranberry juice contains proanthocyanidins that block adherence of pathogens to uroepithelial cells in vitro (Foo et al, 2000). Randomized trials in low-risk patients show that 200 to 750 mL daily of cranberry or lingonberry juice or cranberry-concentrate tablets reduce the risk of symptomatic, recurrent infection by 12% to 20% (Avorn et al, 1994; Kontiokari et al, 2001; Stothers, 2002; McMurdo et al, 2009). However, the actual cranberry content of juices and tablets varies substantially; therefore their efficacy is not predictable (Consumer Reports, 2001; Klein, 2002). Furthermore, other trials of cranberry products show no benefit and there is no evidence that they are effective for treatment of UTIs (Jepson et al, 2001; Raz et al, 2004).

Other factors, such as hygiene, frequency and timing of voiding, wiping patterns, use of hot tubs, and type of undergarments, have not been shown to predispose women to recurrent infection, and there is no rationale for giving women specific instructions regarding them.

KEY POINTS: BLADDER INFECTIONS

- Uncomplicated cystitis should be treated for 3 days.
- Asymptomatic bacteriuria should be treated only in pregnant women and prior to urologic intervention.
- Recurrent UTIs caused by bacterial persistence require urologic management; reinfections can be managed medically.

KIDNEY INFECTIONS

Renal Infection (Bacterial Nephritis)

Although renal infection is less prevalent than bladder infection, it often is a more difficult problem for the patient and his or her physician because of its often varied and morbid presentation and course, the difficulty in establishing a firm microbiologic and pathologic diagnosis, and its potential for significantly impairing renal function. Although the classic symptoms of acute onset of fever, chills, and flank pain are usually indicative of renal infection, some patients with these symptoms do not have renal infection. Conversely, significant renal infection may be associated with an insidious onset of nonspecific local or systemic symptoms, or it may be entirely asymptomatic. Therefore a high clinical index of suspicion and appropriate radiologic and laboratory studies are required to establish the diagnosis of renal infection.

Unfortunately, the relationship between laboratory findings and the presence of renal infection often is poor. Bacteriuria and pyuria, the hallmarks of UTI, are not predictive of renal infection. Conversely, patients with significant renal infection may have sterile urine if the ureter draining the kidney is obstructed or the infection is outside of the collecting system.

The pathologic and radiologic criteria for diagnosing renal infection may also be misleading. Interstitial renal inflammation, once thought to be caused predominantly by bacterial infection, is now recognized as a nonspecific histopathologic change associated with a variety of immunologic, congenital, or chemical lesions that usually develop in the absence of bacterial infection. Infectious granulomatous diseases of the kidney often have either radiologic or pathologic characteristics that mimic renal cystic disease, neoplasia, or other renal inflammatory disease.

The effect of renal infection on renal function is varied. Acute or chronic pyelonephritis may transiently or permanently alter renal function, but nonobstructive pyelonephritis is no longer recognized as a major cause of renal failure (Baldassarre and Kaye, 1991; Fraser et al, 1995). However, pyelonephritis, when associated with urinary tract obstruction or granulomatous renal infection, may lead rapidly to significant inflammatory complications, renal failure, or even death.

Pathology

The opportunity for pathologic confirmation of acute bacterial nephritis is rare. The kidney may be edematous. Focal acute suppurative bacterial nephritis caused by hematogenous dissemination of bacteria to the renal cortex is characterized by multiple focal areas of suppuration on the surface of the kidney (Fig. 12-15). Histologic examination of the renal cortex shows focal suppurative destruction of glomeruli and tubules. Adjacent cortical structures and the medulla are not involved in the inflammatory reaction. Acute ascending pyelonephritis is characterized by linear bands of inflammation extending from the medulla to the renal capsule (Fig. 12-16). Histologic examination usually reveals a focal wedge-shaped area of acute interstitial inflammation with the apex of the wedge in the renal medulla. Polymorphonuclear leukocytes or a predominantly lymphocytic and plasma cell response are seen. Bacteria also may be present.

The changes that appear to be most specific for chronic pyelonephritis are evident on careful gross examination of the kidney and consist of a cortical scar associated with retraction of the corresponding renal papilla (Hodson, 1965; Hodson and Wilson, 1965; Heptinstall, 1974; Freedman, 1979). The kidney shows evidence of patchy involvement with numerous chronic inflammatory foci mainly confined to the cortex but also involving the medulla (Fig. 12-17).

The scars may be separated by intervening zones of normal parenchyma, causing a grossly irregular renal outline. The microscopic appearance, as with most chronic interstitial disease, includes the presence of lymphocytes and plasma cells. Although glomeruli within scars may be surrounded by a cuff of fibrosis or be partially

In: Gillenwater JY, Grayhack JT, Howards SS, et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

or completely hyalinized, glomeruli outside these severely scarred zones are relatively normal. Vascular involvement is variable, but in patients with hypertension, nephrosclerosis may be found. Papillary abnormalities include deformity, sclerosis, and sometimes necrosis. Studies in animals have clearly indicated the critical role of the papilla in the initiation of pyelonephritis (Freedman and Beeson, 1958). However, these changes are not necessarily specific for bacterial infection and may occur in the absence of infection as

a result of other disorders such as analgesic abuse, diabetes, and sickle cell disease.

Acute Pyelonephritis

Although pyelonephritis is defined as inflammation of the kidney and renal pelvis, the diagnosis is clinical. True infection of the “upper urinary tract” can be proved by catheterization tests (ureteral

Figure 12-17. Chronic pyelonephritis. The renal cortex shows thickened fibrous capsule and focal retracted scar on surface of kidney. Focal destruction of tubules in center of picture is accompanied by periglomerular fibrosis and scarring. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY, Grayhack JT, Howards SS, et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

Figure 12-18. Brightfield micrograph of a mixed bacterial leukocyte cast from patient with acute pyelonephritis. Only the bacteria and the nucleus of a leukocyte stain strongly. Many bacteria are clearly demonstrated by through-focusing (toluidine blue O stain, magnification $\times 640$). (From Lindner LE, Jones RN, Haber MH. A specific urinary cast in acute pyelonephritis. *Am J Clin Pathol* 1980;73:809–11.)

catheterization or bladder washout) as described in this chapter, but these are impractical and unnecessary in most patients with acute pyelonephritis. None of the noninvasive tests that have been developed to determine infection in the kidney or bladder are totally reliable.

Clinical Presentation. The clinical spectrum ranges from gram-negative sepsis to cystitis with mild flank pain (Stamm and Hooton, 1993). The classic presentation is an abrupt onset of chills, fever (100.3°F or greater), and unilateral or bilateral flank or costovertebral angle pain and/or tenderness. These so-called upper tract signs are often accompanied by dysuria, increased urinary frequency, and urgency.

Although some authors regard loin pain and fever in combination with significant bacteriuria as diagnostic of acute pyelonephritis, it is clear from localization studies using ureteral catheterization (Stamey and Pfau, 1963) or the bladder washout technique (Fairley et al, 1967) that clinical symptoms correlate poorly with the site of infection (Stamey et al, 1965; Eykyn et al, 1972; Fairley, 1972; Smeets and Gower, 1973).

In a large study of 201 women and 12 men with recurrent UTIs, Busch and Huland (1984) showed that fever and flank pain are no more diagnostic of pyelonephritis than they are of cystitis. Of patients with flank pain and/or fever, over 50% had lower tract bacteriuria. Conversely, patients with bladder symptoms or no symptoms frequently had upper tract bacteriuria. Approximately 75% of patients give a history of previous lower UTIs.

On physical examination, there often is tenderness to deep palpation in the costovertebral angle. Variations of this clinical presentation have been recognized. Acute pyelonephritis may also simulate gastrointestinal tract abnormalities with abdominal pain, nausea, vomiting, and diarrhea. Asymptomatic progression of acute pyelonephritis to chronic pyelonephritis, particularly in compromised hosts, may occur in the absence of overt symptoms. Acute renal failure may be present in the rare case (Richet and Mayaud, 1978; Olsson et al, 1980).

Laboratory Diagnosis. The patient may have leukocytosis with a predominance of neutrophils. Urinalysis usually reveals numerous WBCs, often in clumps, and bacterial rods or chains of cocci. Leukocytes exhibiting brownian motion in the cytoplasm (glitter cells) may be present if the urine is hypotonic, but they are not in themselves diagnostic of pyelonephritis. The presence of large amounts of granular or leukocyte casts in the urinary sediment is suggestive of acute pyelonephritis. A specific type of urinary cast characterized by the presence of bacteria in its matrix has been demonstrated in the urine of patients who have had acute

pyelonephritis (Fig. 12-18) (Lindner et al, 1980). Bacteria in the casts were not easily distinguished by simple brightfield microscopy without special staining of the sediment. Staining of the sediment with a basic dye such as dilute toluidine blue or KOVA stain (I.C.L. Scientific, Fountain Valley, CA) demonstrated the bacteria in casts without difficulty. Blood tests may show leukocytosis with a predominance of neutrophils, increased erythrocyte sedimentation rate, elevated C-reactive protein levels, and elevated creatinine levels if renal failure is present. In addition, creatinine clearance may be decreased. Blood cultures may be positive.

Bacteriology. Urine cultures are positive, but about 20% of patients have urine cultures with fewer than 10^5 cfu/mL and therefore negative results on Gram staining of the urine (Rubin et al, 1992).

E. coli, which constitutes a unique subgroup that possesses special virulence factors, accounts for 80% of cases. If vesicoureteral reflux is absent, a patient bearing the P blood group phenotype may have special susceptibility to recurrent pyelonephritis caused by *E. coli* that have P pili and bind to the P blood group antigen receptors (Lomborg et al, 1983). Bacterial K antigens and endotoxins also may contribute to pathogenicity (Kaijser et al, 1977). Many cases of community-acquired pyelonephritis are caused by a limited number of multiantimicrobial-resistant clonal groups (Manges et al, 2004).

More resistant species, such as *Proteus*, *Klebsiella*, *Pseudomonas*, *Serratia*, *Enterobacter*, or *Citrobacter*, should be suspected in patients who have recurrent UTIs, are hospitalized, or have indwelling catheters, as well as in those who required recent urinary tract instrumentation. Except for *E. faecalis*, *S. epidermidis*, and *S. aureus*, gram-positive bacteria rarely cause pyelonephritis.

Blood cultures are positive in about 25% of cases of uncomplicated pyelonephritis in women, and the majority replicate the urine culture and do not influence decisions regarding therapy. Therefore blood cultures should not be routinely obtained for the evaluation of uncomplicated pyelonephritis in women. However, they should be performed in men and women with systemic toxicity or in those requiring hospitalization or with risk factors such as pregnancy (Velasco et al, 2003).

Renal Ultrasonography and Computed Tomography. These studies are commonly used to evaluate patients initially for complicated UTIs or factors or to reevaluate patients who do not respond after 72 hours of therapy (see later). Ultrasonography (Fig. 12-19) and CT show renal enlargement, hypoechoic or attenuated parenchyma, and a compressed collecting system. They also

may delineate focal bacterial nephritis and obstruction. When parenchymal destruction becomes pronounced, a more disorganized parenchyma and abscess formation associated with complicated renal and perirenal infections may be identified (Soulén et al, 1989).

Differential Diagnosis. Acute appendicitis, diverticulitis, and pancreatitis can cause a similar degree of pain, but the location of the pain often is different. Results of the urine examination are usually normal. Herpes zoster can cause superficial pain in the region of the kidney but is not associated with symptoms of UTI; the diagnosis will be apparent when shingles appear.

Management

Initial Management. Infection in patients with acute pyelonephritis can be subdivided into (1) uncomplicated infection that does not warrant hospitalization, (2) uncomplicated infection in patients

Figure 12-19. Acute pyelonephritis. Ultrasound image of the right kidney demonstrates renal enlargement, hypoechoic parenchyma, and compressed central collecting complex (arrows). (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JT, Grayhack JT, Howards SS, et al, editors. *Adult and pediatric urology*. Philadelphia: Lippincott William & Wilkins; 2002. p. 211–72.)

with normal urinary tracts who are ill enough to warrant hospitalization for parenteral therapy, and (3) complicated infection associated with hospitalization, catheterization, urologic surgery, or urinary tract abnormalities (Fig. 12-20).

It is critical to determine whether the patient has an uncomplicated or complicated UTI because significant abnormalities have been found in 16% of patients with acute pyelonephritis (Shen and Brown, 2004). In patients with presumed uncomplicated pyelonephritis who will be managed as outpatients, initial radiologic evaluation can usually be deferred. However, if there is any reason to suspect a problem or if the patient will not have reasonable access to imaging if there should be no change in condition, we prefer renal ultrasonography to rule out stones or obstruction. In patients with known or suspected complicated pyelonephritis, CT provides excellent assessment of the status of the urinary tract and the severity and extent of the infection.

For patients who will be managed as outpatients, single-drug oral therapy with a fluoroquinolone is more effective than TMP-SMX for patients with domiciliary infections (Talan et al, 2000). Many physicians administer a single parenteral dose of an antimicrobial agent (ceftriaxone, gentamicin, or a fluoroquinolone) before initiating oral therapy (Israel et al, 1991; Pinson et al, 1994). If a gram-positive organism is suspected, amoxicillin or amoxicillin/clavulanic acid is recommended (Warren et al, 1999).

If a patient has an uncomplicated infection but is sufficiently ill to require hospitalization (high fever, high WBC count, vomiting, dehydration, evidence of sepsis), has complicated pyelonephritis, or fails to improve during the initial outpatient treatment period, a parenteral fluoroquinolone, an aminoglycoside with or without ampicillin, or an extended-spectrum cephalosporin with or without an aminoglycoside is recommended (Warren et al, 1999) (Table 12-15). If gram-positive cocci are causative, ampicillin/sulbactam with or without an aminoglycoside is recommended.

Hospitalization, IV fluids, and antipyretics are required.

An obstructed kidney has difficulty concentrating and excreting antimicrobial agents. Any substantial obstruction must be relieved expediently by the safest and simplest means.

A Gram stain of the urine sediment is helpful to guide the selection of the initial empirical antimicrobial therapy. In all cases,

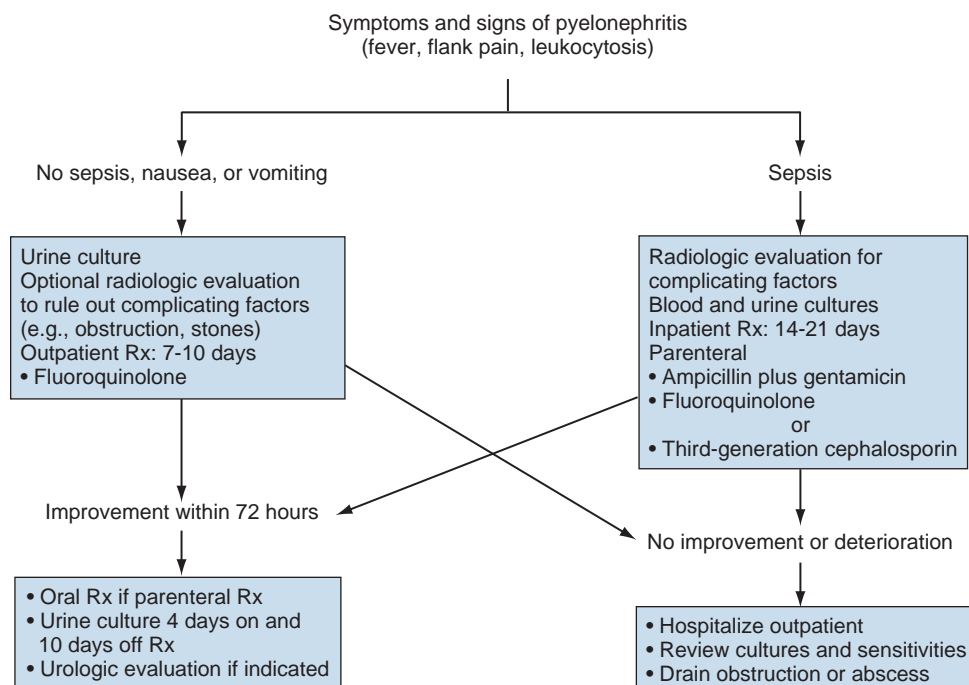

Figure 12-20. Management of acute pyelonephritis.

TABLE 12-15 Treatment Regimens for Acute Complicated and Uncomplicated Pyelonephritis in Women

CIRCUMSTANCES	ROUTE	DRUG	DOSAGE	FREQUENCY PER DOSE	DURATION (DAYS)
Outpatient—moderately ill, no nausea or vomiting	Oral	TMP-SMX DS	160-800 mg	bid	10-14
		Ciprofloxacin	500 mg	bid	3-7
		Levofloxacin	500 mg	qd	
Inpatient—severely ill, possible sepsis	Parenteral	Ampicillin and gentamicin	1 g	qid	14
			1.5 mg/kg	tid	
		Ciprofloxacin	400 mg	bid	10
		Levofloxacin	500 mg	qd	
		Ceftriaxone	1 to 2g	qd	
					Take until afebrile, then take oral
Pregnant	Parenteral	Ampicillin and gentamicin	1 g	qid	Take until afebrile, then take oral
			1 mg/kg	tid	
		Aztreonam	1 g	tid-qid	
	Oral	Cephalexin	500 mg	bid	

DS, double strength; TMP-SMX, trimethoprim-sulfamethoxazole.

Modified from Stamm WE, Hooton TM. Management of urinary tract infections in adults. *N Engl J Med* 1993;329:1328-34. Copyright 1993, Massachusetts Medical Society. All rights reserved.

antimicrobial therapy should be active against potential uropathogens and achieve antimicrobial levels in renal tissue and urine.

Subsequent Management. Even though the urine usually becomes sterile within a few hours of starting antimicrobial therapy, patients with acute uncomplicated pyelonephritis may continue to have fever, chills, and flank pain for several more days after initiation of successful antimicrobial therapy (Behr et al, 1996). They should be observed.

Ambulatory patients should be treated with a fluoroquinolone for 7 days (Talan et al, 2000). Fluoroquinolone therapy is associated with greater bacteriologic and clinical cure rates than 14-day TMP-SMX therapy (Talan et al, 2000). Alterations in antimicrobial therapy may be made depending on the patient's clinical response and the results of the culture and susceptibility tests. Susceptibility tests should also be used to replace potentially toxic drugs, such as aminoglycosides, with less toxic drugs, such as the fluoroquinolones, aztreonam, and cephalosporins.

Patients with complicated pyelonephritis and positive blood cultures should be treated with parenteral therapy until clinically stable. If blood cultures are negative, 2- to 3-day parenteral therapy is sufficient. Following parenteral therapy, an appropriate oral antimicrobial drug (fluoroquinolone, TMP, TMP-SMX, or amoxicillin or amoxicillin/clavulanic acid for gram-positive organisms) should be continued in full dosage for an additional 10 to 14 days.

Unfavorable Response to Therapy. When the response to therapy is slow or the urine continues to show infection, an immediate reevaluation is mandatory. Urine and blood cultures must be repeated and appropriate alterations in antimicrobial therapy made on the basis of susceptibility testing. CT is indicated to attempt to identify unsuspected obstructive uropathy, abscess formation, urolithiasis, or underlying anatomic abnormalities that may have predisposed the patient to infection, prevented a rapid therapeutic response, or caused complications of the infectious process, such as renal or perinephric abscess. **In patients with fever lasting longer than 72 hours, CT is most helpful for ruling out obstruction and identifying renal and perirenal infections (Soulen et al, 1989).** Radionuclide imaging may be useful to demonstrate functional changes associated with acute pyelonephritis (decrease in renal blood flow, delay in peak function, and delay in excretion of the

radionuclide) (Fischman and Roberts, 1982) and cortical defects associated with vesicoureteral reflux.

Follow-Up. Repeat urine cultures should be performed on the fifth to the seventh day of therapy and 10 to 14 days after discontinuing antimicrobial therapy to ensure that the urinary tract remains free of infections. Between 10% and 30% of individuals with acute pyelonephritis relapse after a 14-day course of therapy. Patients who relapse usually are cured by a second 14-day course of therapy, but occasionally a 6-week course is necessary (Tolkoff-Rubin et al, 1984; Johnson and Stamm, 1987).

Depending on the clinical presentation and response and initial urologic evaluation, some patients may require additional evaluation (e.g., voiding cystourethrogram, cystoscopy, bacterial localization studies) and correction of an underlying abnormality of the urinary tract. Raz and colleagues (2003) evaluated the long-term impact of acute pyelonephritis in women. Scanning with ^{99m}Tc-dimercaptosuccinic acid (^{99m}Tc-DMSA) 10 to 20 years after acute pyelonephritis revealed scars in approximately 50% of the patients, but changes in renal function were minimal and not associated with renal scarring.

Acute Focal or Multifocal Bacterial Nephritis

Acute focal or multifocal bacterial nephritis is an uncommon, severe form of acute renal infection in which a heavy leukocyte infiltrate is confined to a single renal lobe (focal) or multiple lobes (multifocal).

Clinical Presentation. The clinical presentation of patients with acute bacterial nephritis is similar to that of patients with acute pyelonephritis but usually is more severe. About half of the patients are diabetic, and sepsis is common. Generally, leukocytosis and UTI resulting from gram-negative organisms are found; more than 50% of the patients are bacteremic (Wicks and Thornbury, 1979). There is growing evidence that acute focal bacterial nephritis (AFBN) represents a midpoint on the spectrum between pyelonephritis and renal abscess.

Radiologic Findings. The diagnosis must be made by radiologic examination. The mass has slightly less nephrographic density than the surrounding normal renal parenchyma.

Ultrasonography and CT establish the diagnosis. On ultrasonography, the lesion is typically poorly margined and relatively sonolucent with occasional low-amplitude echoes that disrupt the cortical medullary junction (Corriere and Sandler, 1982) (Fig. 12-21A). Enhancement with a contrast agent is necessary with CT studies because the lesion is difficult to visualize on the unenhanced study (Fig. 12-21B). Wedge-shaped areas of decreased enhancement are seen. No definite wall is evident, and frank liquefaction is absent. Conversely, abscesses tend to have liquid centers, are usually round, and are present both before and after contrast medium enhancement. More chronic abscesses may also show a ring-shaped area of increased enhancement surrounding the lesion (Corriere and Sandler, 1982). Gallium scanning reveals uptake that is in the region of and larger than the previously demonstrated mass (Rosenfield et al, 1979). In patients with multifocal disease, the findings are similar but multiple lobes are involved.

Management. Acute bacterial nephritis probably represents a relatively early phase of frank abscess formation. In a series of cases reported by Lee and coworkers (1980), a patient with acute focal bacterial nephritis progressed to abscess formation. McCoy and associates reported radiographically proven progression from acute nephritis to an abscess despite appropriate medical management (McCoy et al, 1985). Shimizu and colleagues presented a case of a 16-year-old female with CT imaging consistent with AFBN and no evidence of drainable fluid collection, which progressed by hospital day 13 to a hypodense large abscess in the area previously seen to be nephritis while being treated (Shimizu et al, 2005). Treatment includes hydration and IV antimicrobial agents for at least 7 days, followed by 7 days of oral antimicrobial therapy. Patients with bacterial nephritis typically respond to medical therapy, and follow-up studies will show resolution of the wedge-shaped zones of diminished attenuation. Failure to respond to antimicrobial therapy is an indication for appropriate studies to rule out obstructive uropathy, renal or perirenal abscess, renal carcinoma, or acute renal vein thrombosis. Long-term follow-up studies performed in a few patients with multifocal disease have demonstrated a decrease in renal size and focal calyceal deformities suggestive of papillary necrosis (Davidson and Talner, 1978).

Emphysematous Pyelonephritis

Emphysematous pyelonephritis is a urologic emergency characterized by an acute necrotizing parenchymal and perirenal

infection caused by gas-forming uropathogens. The pathogenesis is poorly understood. Because the condition usually occurs in diabetic patients, it has been postulated that the high tissue glucose levels provide the substrate for microorganisms such as *E. coli*, which are able to produce carbon dioxide by the fermentation of sugar (Schainuck et al, 1968). Although glucose fermentation may be a factor, the explanation does not account for the rarity of emphysematous pyelonephritis despite the high frequency of gram-negative UTI in diabetic patients, nor does it explain the rare occurrence of the condition in nondiabetic patients.

In addition to diabetes, many patients have urinary tract obstruction associated with urinary calculi or papillary necrosis and significant renal functional impairment. The overall mortality rate has been reported to be between 19% (Huang and Tseng, 2000) and 43% (Freiha et al, 1979).

Clinical Presentation. Nearly all of the documented cases of emphysematous pyelonephritis have occurred in adults (Hawes et al, 1983). Juvenile diabetic patients do not appear to be at risk. Women are affected more often than men.

The usual clinical presentation is severe, acute pyelonephritis, although in some instances a chronic infection precedes the acute attack. Almost all patients display the classic triad of fever, vomiting, and flank pain (Schainuck et al, 1968). Pneumaturia is absent unless the infection involves the collecting system. Results of urine cultures are invariably positive. *E. coli* is most commonly identified. *Klebsiella* and *Proteus* are less common.

Radiologic Findings. The diagnosis is established radiographically. Tissue gas that is distributed in the parenchyma may appear on abdominal radiographs as mottled gas shadows over the involved kidney (Fig. 12-22). This finding is often mistaken for bowel gas. A crescentic collection of gas over the upper pole of the kidney is more distinctive. As the infection progresses, gas extends to the perinephric space and retroperitoneum. This distribution of gas should not be confused with cases of emphysematous pyelitis in which air is in the collecting system of the kidney. Emphysematous pyelitis is secondary to a gas-forming bacterial UTI, often occurs in nondiabetic patients, is less serious, and usually responds to antimicrobial therapy.

Ultrasonography usually demonstrates strong focal echoes suggesting the presence of intraparenchymal gas (Brenbridge et al, 1979; Conrad et al, 1979). CT is the imaging procedure of choice in defining the extent of the emphysematous process and guiding management (Figs. 12-23 and 12-24). An absence of fluid in CT

Figure 12-21. Acute focal bacterial nephritis. A, Ultrasound image; longitudinal view of the left kidney demonstrates spleen (S) and left kidney (arrows). Note irregular midpole mass (M) of slightly higher echo texture than surrounding normal renal parenchyma. B, Contrast medium-enhanced computed tomography scan demonstrates a wedge-shaped area of low density (arrows) in the middle portion of the left kidney. The findings resolved after antimicrobial therapy. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY, Grayhack JT, Howards SS, et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211-72.)

images or the presence of streaky or mottled gas with or without bubbly and loculated gas appears to be associated with rapid destruction of renal parenchyma and a 50% to 60% mortality rate (Wan et al, 1996; Best et al, 1999). The presence of renal or perirenal fluid, the presence of bubbly or loculated gas or gas in the collecting system, and the absence of streaky or mottled gas patterns

Figure 12-22. Emphysematous pyelonephritis; plain film. Extensive perinephric (*long arrows*) and intraparenchymal (*short arrows*) gas secondary to acute bacterial pyelonephritis. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY, Grayhack JT, Howards SS, et al, editors. Adult and pediatric urology. Philadelphia: Lippincott William & Wilkins; 2002. p. 211–72.)

are associated with a less than 20% mortality rate. Obstruction is demonstrated in approximately 25% of the cases. A nuclear renal scan should be performed to assess the degree of renal function impairment in the involved kidney and the status of the contralateral kidney.

Management. Emphysematous pyelonephritis is a surgical emergency. Most patients are septic, and fluid resuscitation and broad-spectrum antimicrobial therapy are essential. If the kidney is functioning, medical therapy can be considered (Wan et al, 1996; Best et al, 1999). Nephrectomy is recommended for patients who do not improve after a few days of therapy (Malek and Elder, 1978). If the affected kidney is nonfunctioning and not obstructed, nephrectomy should be performed because medical treatment alone is usually lethal. If a kidney is obstructed, catheter drainage must be instituted. If the patient's condition improves, nephrectomy may be deferred pending a complete urologic evaluation. Although there are isolated case reports of retention of renal function after medical therapy combined with relief of obstruction, most patients require nephrectomy (Hudson et al, 1986).

Renal Abscess

Renal abscess or carbuncle is a collection of purulent material confined to the renal parenchyma. Before the antimicrobial era, 80% of renal abscesses were attributed to hematogenous seeding by staphylococci (Campbell, 1930). Additionally, patients historically presenting with abscesses were young men with no prior renal disease. Although experimental and clinical data document the facility for abscess formation in normal kidneys after hematogenous inoculation with staphylococci, widespread use of antimicrobial agents since about 1950 appears to have diminished the propensity for gram-positive abscess formation (DeNavasquez, 1950; Cotran, 1969). The current index patient typically has a history of renal disease or obstruction, has no gender predominance and no laterality, and the infection is typically with a gram-negative organism.

Since about 1970, gram-negative organisms have been implicated in the majority of adults with renal abscesses. Hematogenous renal seeding by gram-negative organisms may occur, but this is not likely to be the primary pathway for gram-negative abscess formation. Clinically, there is no evidence that gram-negative septicemia antedates most lesions. Further, gram-negative hematogenous pyelonephritis is virtually impossible to produce in animals unless the kidney is traumatized or completely obstructed (Cotran, 1969; Timmons and Perlmutter, 1976). Like the normal kidney, the

Figure 12-23. Type I emphysematous pyelonephritis with complete renal destruction in a 49-year-old woman. A, Computed tomography (CT) scan of the right kidney shows complete destruction with gas (*arrowheads*) extending beyond the renal fascia. B, CT scan with a modified lung window display shows the characteristic streaky gas in the completely destroyed kidney. The patient died on arrival in the emergency department. (From Wan YL, Lee TY, Bullard MJ, et al. Acute gas-producing bacterial renal infection: correlation between imaging findings and clinical outcome. Radiology 1996;198:433–8.)

Figure 12-24. Type II emphysematous pyelonephritis in a 57-year-old woman. A, Radiograph shows crescent-shaped (white arrowheads) and loculated (black arrows) gas in the right renal area. B, Computed tomography scan obtained after administration of contrast material shows a low-attenuation area (arrowheads) in the right kidney due to acute pyelonephritis, as well as a subcapsular abscess with fluid and bubbly and loculated gas. The patient survived after percutaneous drainage was performed. (From Wan YL, Lee TY, Bullard MJ, et al. Acute gas-producing bacterial renal infection: correlation between imaging findings and clinical outcome. *Radiology* 1996;198:433–8.)

partially obstructed kidney rejects blood-borne gram-negative inocula. Thus ascending infection associated with tubular obstruction from prior infections or calculi appears to be the primary pathway for the establishment of gram-negative abscesses. Two-thirds of gram-negative abscesses in adults are associated with renal calculi or damaged kidneys (Salvatierra et al, 1967; Siegel et al, 1996). Although the association of pyelonephritis with vesicoureteral reflux is well established, the association of renal abscess with vesicoureteral reflux has been infrequently noted (Segura and Kelalis, 1973). Case reports in the pediatric literature exist, but literature within the adult population is sparse. More recent observations, however, indicate that reflux is frequently associated with renal abscesses and persists long after sterilization of the urinary tract (Timmons and Perlmutter, 1976; Anderson and McAninch, 1980).

Clinical Presentation. The patient may present with fever, chills, abdominal or flank pain, and occasionally weight loss and malaise. Symptoms of cystitis may occur. Occasionally, these symptoms may be vague and delay diagnosis until surgical exploration or, in more severe cases, autopsy (Anderson and McAninch, 1980). A thorough history may reveal a gram-positive source of infection 1 to 8 weeks before the onset of urinary tract symptoms or symptoms consistent with UTI or pyelonephritis in the weeks prior (Hung et al, 2007). The infection may have occurred in any area of the body. Multiple skin carbuncles and IV drug abuse introduce gram-positive organisms into the bloodstream. Other common sites are the mouth, lungs, and bladder (Lyons et al, 1972). Complicated UTIs associated with stasis, calculi, pregnancy, neurogenic bladder, and diabetes mellitus also appear to predispose the patient to abscess formation (Anderson and McAninch, 1980).

Laboratory Diagnosis. The patient typically has marked leukocytosis. In Siegel and associates' (1996) series of 52 patients, blood cultures were positive 28% of the time, while Yen and colleagues (1999) published a series of 78 patients, 25 of which (32%) had positive blood cultures. When comparing positive cultures in all three types of fluids (abscess, blood, urine) only 1 patient of the 78 had identical isolates in all three. Urine and abscess culture had a 15% identical culture rate, whereas blood and abscess had a 13% identical culture rate (Yen et al, 1999). Pyuria and bacteriuria may not be evident unless the abscess communicates with the collecting system. Because gram-positive organisms are most commonly blood-borne, urine cultures in these cases typically show no

Figure 12-25. Acute renal abscess. Transverse ultrasound image of the right kidney demonstrates a poorly margined rounded focal hypoechoic mass (arrows) in the anterior portion of the kidney.

growth or a microorganism different from that isolated from the abscess. Another study showed not only a bacteremia rate of 26% but also that positive urine cultures were only present in roughly 30% of patients (Shu et al, 2004).

Ultrasonography and CT distinguish abscess from other inflammatory renal diseases. Ultrasonography is the quickest and least expensive method to demonstrate a renal abscess. An echo-free or low-echodensity space-occupying lesion with increased transmission is found on the ultrasound image (Fig. 12-25). The margins of an abscess are indistinguishable in the acute phase, but the structure contains a few echoes and the surrounding renal parenchyma is edematous (Fiegler, 1983). Subsequently, the appearance tends to be that of a well-defined mass. The internal appearance, however, may vary from a virtually solid lucent mass to one with large numbers of low-level internal echoes (Schneider et al, 1976). The number of echoes depends on the amount of cellular debris within the abscess. The presence of air results in

a strong echo with a shadow. Differentiation between an abscess and a tumor is impossible in many cases. Arteriography is used infrequently to demonstrate abscesses. The center of the mass tends to be hypervascular or avascular, with increased vascularity at the cortical margins and lack of vascular displacement and neovascularity.

CT appears to be the diagnostic procedure of choice for renal abscesses because it provides excellent delineation of the tissue. On CT, abscesses are characteristically well defined both before and after contrast agent enhancement. The findings depend in part on the age and severity of the abscess (Baumgarten and Baumgartner, 1997). Initially, CT shows renal enlargement and focal, rounded areas of decreased attenuation (Fig. 12-26). After several days of the onset of the infection, a thick fibrotic wall begins to form around the abscess. An echo-free or slightly echogenic mass caused by the presence of necrotic debris is seen. CT of a chronic abscess shows obliteration of adjacent tissue planes, thickening of the Gerota fascia, a round or oval parenchymal mass of low attenuation, and a surrounding inflammatory wall of slightly higher attenuation that forms a ring when the scan is enhanced with contrast material (Fig. 12-27). The ring sign is caused by the increased vascularity of the abscess wall (Callen, 1979; Gerzof and Gale, 1982).

Radionuclide imaging with gallium or indium is sometimes useful in evaluating patients with renal abscesses (see prior sections in this chapter and Chapter 2).

Management. Although the classic treatment for an abscess has been percutaneous or open incision and drainage, there is good evidence that use of IV antimicrobial agents and careful observation of a small abscess less than 3 cm or even 5 cm in a clinically stable patient is appropriate. Antibiotics, if begun early enough in the course of the process, may obviate surgical procedures (Hoverman et al, 1980; Levin et al, 1984; Shu et al, 2004). CT- or ultrasound-guided needle aspiration may be necessary to differentiate an abscess from a hypervascular tumor. Aspirated material should be cultured and appropriate antimicrobial therapy instituted on the basis of the findings.

All patients should be immediately started on IV antibiotic therapy. The selection of empirical antimicrobial therapy is dependent on the presumed source of the infection and the resistance patterns within the hospital. When hematogenous

dissemination is suspected, the pathogenic organism most frequently is penicillin-resistant *Staphylococcus*, and the antimicrobial of choice therefore is a penicillinase-resistant penicillin (Schiff et al, 1977). If a history of penicillin hypersensitivity is present, the recommended drug is vancomycin. Cortical abscesses that occur in the abnormal urinary tract are associated with more typical gram-negative pathogens secondary to ascending infection and should be treated empirically with IV third-generation cephalosporins, antipseudomonal penicillins, or aminoglycosides until specific therapy can be instituted. Patients should have serial examinations with ultrasonography or CT until the abscess resolves. The radiographic evolution or resolution of the abscesses will typically further dictate clinical management. The suspicion of misdiagnosis or an uncontrolled infection with the development of perinephric abscess or infection with an organism resistant to the antimicrobial agents used in therapy should be suspected with worsening clinical picture.

After patients are started on IV antibiotic therapy and there is radiographic confirmation of abscess, the size of the abscess typically dictates management. Abscesses 3 cm or less can be managed with antibiotics alone (Shu et al, 2004; Lee et al, 2010; Siegel et al, 1996). In a series from South Korea of 49 patients with normal urinary tracts and abscesses less than 5 cm, there was 100% resolution of abscesses confirmed with CT scan with antibiotics alone (Lee et al, 2010).

Though less data exist for patients with obstruction or anomalous urinary tracts, abscesses 3 to 5 cm in diameter should be

Figure 12-26. Acute renal abscess. Nonenhanced computed tomography scan through the mid pole of the right kidney demonstrates right renal enlargement and an area of decreased attenuation (arrows). After antimicrobial therapy, a follow-up scan showed complete regression of these findings.

Figure 12-27. Chronic renal abscess. A, Enhanced computed tomography scan shows an irregular septated low-density mass (M) extensively involving the left kidney. Note thickening of perinephric fascia (arrows) and extensive compression of the renal collecting system. Findings are typical of renal abscess. B, Ultrasound longitudinal image demonstrates a septated hypoechoic mass (M) occupying much of the renal parenchymal volume.

conservatively managed initially in the setting of stable clinical parameters. We suggest following the clinical course and size of the abscess radiographically to assess for improvement. Should the patient progress, percutaneous drainage should be considered. Abscesses of all sizes in immunocompromised hosts or those that do not respond to antimicrobial therapy should be drained percutaneously (Fernandez et al, 1985; Fowler and Perkins, 1994; Siegel et al, 1996). Percutaneous drainage, however, remains the first-line procedure of choice for most renal abscesses greater than 5 cm in diameter. Typically, abscesses of this size require multiple drains, multiple drain manipulations, or eventual surgical washout and potential nephrectomy (Siegel et al, 1996).

Infected Hydronephrosis and Pyonephrosis

Infected hydronephrosis is bacterial infection in a hydronephrotic kidney. The term *pyonephrosis* refers to infected hydronephrosis associated with suppurative destruction of the parenchyma of the kidney, in which there is total or nearly total loss of renal function (Fig. 12-28). Where infected hydronephrosis ends and pyonephrosis begins is difficult to determine clinically. Rapid diagnosis and treatment of pyonephrosis are essential to avoid permanent loss of renal function and to prevent sepsis.

Clinical Presentation. The patient is usually very ill, with high fever, chills, flank pain, and tenderness. Occasionally, however, a patient may have only an elevated temperature and a complaint of vague gastrointestinal discomfort. A previous history of urinary tract calculi, infection, or surgery is common. Bacteriuria may not be present if the ureter is completely obstructed.

Radiologic Findings. The ultrasonographic diagnosis of infected hydronephrosis depends on demonstration of internal echoes within the dependent portion of a dilated pyelocalyceal system. CT is nonspecific but may show thickening of the renal pelvis, stranding of the perirenal fat, and a striated nephrogram. Ultrasonography demonstrates hydronephrosis and fluid debris levels within the dilated collecting system (Corriere and Sandler, 1982) (Fig. 12-29A). The diagnosis of pyonephrosis is suggested if focal areas of decreased echogenicity are seen within the hydronephrotic parenchyma.

Management. Once the diagnosis of pyonephrosis is made, the treatment is initiated with appropriate antimicrobial drugs and

drainage of the infected pelvis. A ureteral catheter can be passed to drain the kidney, but if the obstruction prevents this, a percutaneous nephrostomy tube should be placed (Camunez et al, 1989) (Fig. 12-29B). When the patient becomes hemodynamically stable, other procedures are usually needed to identify and treat the source of the obstruction.

Perinephric Abscess

Perinephric abscess usually results from rupture of an acute cortical abscess into the perinephric space or from hematogenous seeding from sites of infection. Patients with pyonephrosis,

Figure 12-28. Pyonephrosis: gross specimen. The kidney shows marked thinning of the renal cortex and medulla, suppurative destruction of the parenchyma (arrows), and distention of the pelvis and calyces. Previous incision released a large quantity of purulent material. The ureter showed obstruction distal to the point of section.

Figure 12-29. Pyonephrosis. A, Longitudinal ultrasound image of the right kidney demonstrates echogenic central collecting complex (C) with radiating echogenic septa (arrows) and thinned hypoechoic parenchyma. Multiple dilated calyces (o) with diffuse low-level echoes are seen. B, Antegrade pyelogram performed through a percutaneous nephrostomy catheter correlates well with the ultrasound image. Dilated pus-filled calyces are demonstrated. The renal pelvis is obliterated by chronic scarring and stone disease. The kidney did not regain function. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY, et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

particularly when a calculus is present in the kidney, are susceptible to perinephric abscess formation. Diabetes mellitus is present in approximately one third of patients with perinephric abscess (Edelstein and McCabe, 1988; Meng et al, 2002). In about one third of the cases, perinephric abscess is caused by hematogenous spread, usually from sites of skin infection (Gardiner et al, 2011). A perirenal hematoma can become secondarily infected by the hematogenous route or by direct extension of a primary renal infection. When a perinephric infection ruptures through the Gerota fascia into the paranephric space, the abscess becomes paranephric. Paranephric abscesses may also result from infectious disorders of the bowel, pancreas, or pleural cavity. Conversely, perinephric or psoas abscess may be the result of bowel perforation, Crohn disease, or spread of osteomyelitis from the thoracolumbar spine. *E. coli*, *Proteus*, and *S. aureus* account for most infections.

Clinical Presentation. The onset of symptoms is typically insidious. Symptoms are present for more than 5 days in most patients with perinephric abscess compared with only about 10% of patients with pyelonephritis. The clinical presentation may be similar to that of pyelonephritis; however, more than one third of patients may be afebrile. An abdominal or flank mass can be felt in about half of the cases; costovertebral angle tenderness is typically present. Psoas abscess should be suspected if the patient has a limp and flexion and external rotation of the ipsilateral hip. Laboratory features include leukocytosis, elevated levels of serum creatinine, and pyuria in more than 75% of cases. Edelstein and McCabe (1988) showed that results of urine cultures predicted perinephric abscess isolates in only 37% of cases; a blood culture, particularly with multiple organisms, was often indicative of perinephric abscess but identified all organisms in only 42% of cases. Meng et al (2002) showed that roughly 75% of patients had a positive culture. Urine was statistically significantly more sensitive than blood and abscess fluid collection in their study. Therefore caution should be exercised when choosing therapy based on the results of urine and blood cultures because data may sometimes be inadequate. Pyelonephritis usually responds within 4 to 5 days of appropriate antimicrobial therapy; perinephric abscess does not. Thus perinephric abscess should be suspected in a patient with UTI and abdominal or flank mass or persistent fever after 4 days of antimicrobial therapy. Perinephric abscesses are commonly seen concomitantly with renal abscesses.

CT is particularly valuable for demonstrating the primary abscess. In some cases, the abscess is confined to the perinephric space; however, extension to the flank or psoas muscle may occur (Fig. 12-30). CT is able to show with exquisite anatomic detail the route of spread of infection into the surrounding tissues (Fig. 12-31). This information may be helpful in planning the approach for surgical drainage. Ultrasonography demonstrates a diverse appearance ranging from a nearly anechoic mass displacing the kidney to an echogenic collection that tends to blend with normally echogenic fat within the Gerota fascia (Corriere and Sandler, 1982). Occasionally, a retroperitoneal or subdiaphragmatic infection may spread to the paranephric fat that is outside this fascia. The clinical symptoms of insidious onset of fever, flank mass, and tenderness are indistinguishable from those associated with perinephric abscess. UTI, however, is absent. Ultrasonography and CT can usually delineate the abscess outside the Gerota fascia.

Improved imaging techniques have decreased the mortality rate of 40% to 50% in early series to roughly 12%, but there is still an average of 3.4 days' lag time before appropriate diagnosis in a current series (Meng et al, 2002). Only 35% of patients were correctly diagnosed on presentation in the Meng series, and this lag time contributed to mortality in nearly all patients in that series. Having an appropriate threshold for imaging will continue to improve the rate of correct diagnoses.

Management. Antimicrobial agents should be immediately started upon diagnosis of perinephric abscess. Gram stain identifies the pathogenesis and guides antimicrobial therapy. An aminoglycoside together with an antistaphylococcal agent, such as methicillin or oxacillin, should be started immediately. If the

Figure 12-30. Nonenhanced computed tomography scan through the lower pole of the right kidney (previous left nephrectomy) shows extensive perinephric abscess. Extensive abscess (A) distorts and enlarges the renal contour, infiltrates perinephric fat (straight arrows), and also extends into the psoas muscle (asterisk) and the soft tissues of the flank (curved arrow). Also note that normal renal collecting system fat has been obliterated by the process.

Figure 12-31. Perinephric abscess involving the right adrenal gland. Computed tomography scan shows large right pararenal mass (arrows) with multiple low-density areas within. At surgery, a large pararenal abscess with extensive involvement of the right adrenal was found. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY, Grayhack JT, Howards SS, et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

patient has a penicillin hypersensitivity, cephalothin or vancomycin may be used.

In addition to controlling sepsis and preventing further spread of infection, Meng and colleagues' series of 25 patients suggests that, for small perinephric abscesses (<3 cm), antibiotics alone can appropriately treat immune-competent patients (Meng et al, 2002). Eight out of the 10 patients treated with antibiotics alone had full resolution after a mean of 10 days in the hospital. The average size of abscess treated was 1.8 cm. Siegel and coworkers (1996) also showed good resolution of perinephric abscesses less than 3 cm, with cure seen in all five patients in their series.

For larger collections or those not responsive to initial antibiotic therapy, intervention is the next step in treatment. **Surgical drainage, or nephrectomy** if the kidney is nonfunctioning or severely infected, was the classic treatment for perinephric abscesses. However, with the advent of the field of interventional radiology and improvements in percutaneous drainage techniques, renal ultrasonography and CT- or ultrasound-guided percutaneous aspiration and drainage of perirenal collections is now a good option for therapy. In Meng's study, 11 of the 25 patients had percutaneous drainage in addition to antibiotics (Meng et al, 2002). The mean abscess size was 11 cm and the mean time to resolution was 25 days. Four of these patients eventually required open surgical exploration and drainage. All removed kidneys demonstrated hallmarks of minimal function. **Unlike in renal abscesses, early drainage of abscesses greater than 3 cm in diameter is recommended.**

Once the perinephric abscess has been drained, the underlying problem must be dealt with. Some conditions such as renal cortical abscess or enteric communication require prompt attention. Nephrectomy for pyelonephrosis may be performed concurrent with drainage of the perinephric abscess if the patient's condition is good. In other instances it is best to drain the perinephric abscess first and correct the underlying problem or perform a nephrectomy when the patient's condition has improved. Meng's series of 11 patients with abscesses greater than 11 cm had a roughly 33% need for nephrectomy (Meng et al, 2002). Although this is a high number in patients who are likely diabetic where the nephron-sparing approach is ideal, it is decidedly lower than the historical nephrectomy rate, likely secondary to more successful percutaneous drainage rates. In three of their patients with small perinephric abscesses and hydronephrosis, antibiotics and drainage of the obstructed urinary system led to cure.

Perinephric Abscess versus Acute Pyelonephritis. It has already been emphasized that the greatest obstacle to the treatment of perinephric abscess is the delay in diagnosis. In the series of Thorley and colleagues (1974), a common misdiagnosis was acute pyelonephritis; Meng's study showed a similar delay of roughly 3 to 4 days in appropriate diagnosis in a modern study (Meng et al, 2002). Thorley's study found that two factors differentiated perinephric abscess and acute pyelonephritis: (1) most patients with uncomplicated pyelonephritis were symptomatic for less than 5 days before hospitalization, whereas most with perinephric abscesses were symptomatic for longer than 5 days; and (2) no patient with acute pyelonephritis remained febrile for longer than 4 days once appropriate antimicrobial agents were started. All patients with perinephric abscesses had a fever for at least 5 days, with a median of 7 days. Similar results were noted by Fowler and Perkins (1994).

Patients with polycystic renal disease who undergo hemodialysis may be particularly susceptible to the progression from acute UTIs to perinephric abscess. Of 445 patients undergoing chronic hemodialysis at the Regional Kidney Disease Program in Minneapolis, 5.4% had polycystic kidney disease and 33.3% of these patients developed symptomatic UTIs (Sweet and Keane, 1979). Eight (62.5%) developed perinephric abscesses, and three of these patients died. According to the investigators, all UTIs, even those that progressed to perinephric abscesses, were promptly treated with appropriate antimicrobial agents, and all patients in this group became afebrile and asymptomatic when the agents were stopped. Yet later, after various times, symptoms attributable to perinephric abscess developed in eight of the patients. The mechanism of this process is not clear, but the limited bioavailability of some antimicrobial agents in cysts is variable and could contribute to the progression of renal infection.

Chronic Pyelonephritis

In patients without underlying renal or urinary tract disease, chronic pyelonephritis secondary to UTI is a rare disease and an even more rare cause of chronic renal failure. In patients with underlying functional or structural urinary tract abnormalities,

however, chronic renal infection can cause significant renal impairment. Thus it is essential that appropriate studies be used to diagnose, localize, and treat chronic renal infection.

The prevalence of chronic pyelonephritis has also been assessed in patients undergoing dialysis for end-stage renal disease. Despite a 2% to 5% prevalence of bacteriuria in women, pyelonephritis uncomplicated by obstruction or urinary tract malformation does not cause end-stage renal disease. Schechter and colleagues (1971) analyzed the cause for renal failure in 170 patients referred to them for dialysis. Chronic pyelonephritis was the primary cause of end-stage renal disease in 22 (13%) but was usually associated with an underlying structural defect. Unequivocal nonobstructive chronic pyelonephritis was not found. Symptomatic infections tended to occur before the onset of azotemia in most patients with chronic pyelonephritis. Similarly, Huland and Busch (1982) evaluated 161 patients with end-stage renal disease and found that 42 had chronic pyelonephritis. However, in addition to a history of UTIs, these 42 patients had complicating defects, such as vesicoureteral reflux, analgesic abuse, nephrolithiasis, or obstruction. Nonobstructive uncomplicated UTI alone was never found to be the cause of renal insufficiency. Thus, using end-stage renal disease seen at autopsy or at the dialysis clinic as an indicator, the prevalence of uncomplicated chronic bacterial pyelonephritis is rare.

In addition, the role of bacterial infection in development of chronic renal disease can be assessed in patients with renal interstitial and tubular damage similar to that which has classically been called chronic pyelonephritis. The frequency with which various potential causes of interstitial damage are operative in patients with interstitial nephritis was assessed by Murray and Goldberg (1975). These investigators not only concluded that UTI is rarely the sole cause of chronic renal disease in the adult but also observed that 89% of their azotemic patients had a readily identifiable primary cause of their interstitial nephritis. Thus, when patients with a clinical diagnosis of chronic interstitial nephritis are selected as the starting point, it is easy to associate many factors with this disease, but UTI does not seem to be one of them.

Clinical Presentation. There are no symptoms of chronic pyelonephritis until it produces renal insufficiency, and then the symptoms are similar to those of any other form of chronic renal failure. If a patient's chronic pyelonephritis is thought to be an end result of many episodes of acute pyelonephritis, a history of intermittent symptoms of fever, flank pain, and dysuria may be elicited. Similarly, urinary findings and the presence of renal infection correlate poorly. Bacteriuria and pyuria, the hallmarks of UTI, are not predictive of renal infection. Conversely, patients with significant renal infection may have sterile urine if the ureter draining the kidney is obstructed or the infection is outside of the collecting system.

The pathologic and radiologic criteria for diagnosing renal infection may also be misleading. Asscher (1980) has tabulated eight long-term follow-up studies from the literature on kidneys of adults with UTIs. The data from these reports on 901 patients show that bacteriuria present in otherwise healthy adults for long periods may be associated with nonexistent or extremely minimal evidence of kidney damage. Conversely, patients who have chronic pyelonephritis may have negative urine cultures.

Radiologic Findings. The diagnosis of chronic pyelonephritis can be made with the greatest confidence on the basis of pyelographic findings. The essential features are asymmetry and irregularity of the kidney outlines, blunting and dilation of one or more calyces, and cortical scars at the corresponding site (Fig. 12-32). In the absence of stones, obstruction, and tuberculosis, and with the single exception of analgesic nephritis with papillary necrosis (which can be readily excluded by history), chronic pyelonephritis is virtually the only disease that produces a localized scar over a deformed calyx (Stamey, 1980). In advanced pyelonephritis, calyceal distortion and irregularity together with cortical scars complete the picture. Regardless of the etiology of chronic pyelonephritis, CT findings will be consistent with atrophy, cortical/parenchymal thinning, calyceal clubbing, and possible hypertrophy of residual normal tissue and asymmetry (Craig et al, 2008). D'Souza and colleagues (1995) showed a linear relationship between renal

Figure 12-32. Chronic pyelonephritis. Ten-minute excretory urogram demonstrates irregular renal outline with upper pole parenchymal atrophy. Note significant loss of renal cortical thickness over blunted and dilated calyces. Lower pole mass (M) is a simple cyst. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY, Grayhack JT, Howards SS, et al, editors. *Adult and pediatric urology*. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

parenchymal volume loss and function decline as assessed by DMSA scan. Hodson and Wilson (1965) pointed out that renal infarction, an extremely rare condition, may closely resemble pyelonephritic scars but that the renal pyramid remains with renal infarction in contradistinction to pyelonephritis.

Pathology. In chronic pyelonephritis, the gross kidney is often diffusely contracted, scarred, and pitted. The scars are Y-shaped, flat, broad-based depressions with red-brown granular bases. The scarring is often polar with underlying calyceal blunting. The parenchyma is thin, and the corticomedullary demarcation is lost. **Histologic changes are patchy.** There is usually an interstitial infiltrate of lymphocytes, plasma cells, and occasional polymorphonuclear cells. Portions of the parenchyma may be replaced by fibrosis, and, although glomeruli may be preserved, periglomerular fibrosis is often seen. In some affected areas, glomeruli may be completely fibrosed and tubules atrophied. Leukocyte and hyaline casts are sometimes present in the tubules; the latter may cause resemblance to the thyroid colloid, hence the description *renal thyroidization* (Braude, 1973). In general, the changes are nonspecific; they also may be seen in toxic exposures, postobstructive atrophy, hematologic disorders, postirradiation nephritis, ischemic renal disease, and nephrosclerosis.

Management. Management of radiographic evidence of pyelonephritis should be directed at treating infection if present, preventing future infections, and monitoring and preserving renal function. The treatment of existing infection must be based on careful antimicrobial susceptibility tests and selection of drugs that can achieve bactericidal concentrations in the urine and yet are not nephrotoxic. Achievement of acceptable bactericidal levels of a drug in the urine of a patient with chronic pyelonephritis may be difficult because the diminished concentrating ability of pyelonephritis may impair excretion and concentration of the antimicrobial agent. The

duration of antimicrobial therapy is often prolonged to maximize the chance of cure. With patients in whom renal damage develops or progresses in the presence of UTI, the working hypothesis should be that there is an underlying renal, usually papillary, lesion or underlying urologic condition, such as obstruction or calculus, which has increased susceptibility to renal damage. Appropriate nephrologic and urologic evaluation should be undertaken to identify and, if possible, correct these abnormalities.

Bacterial “Relapse” from a Normal Kidney

The concept that bacteria persist in the renal parenchyma between bacteriuric episodes and cause “relapsing” UTIs was based on a study by Turck and colleagues (1968) that suggested that bacterial persistence could be recognized by simply identifying two consecutive recurrent infections with the same organism. Unfortunately, this study did not indicate whether the urine was cultured during therapy to ensure that the original infection had actually been eradicated. It is possible that some of these so-called relapses were in fact unresolved initial infections and that ureteral edema associated with catheterization may have impeded clearance of the initial infecting strain.

Subsequent studies summarized by Stamey (1980) and Forland and associates (1977) have shown that in a normal urinary tract recurrent infections are not caused by relapse from bacterial persistence in the kidney. With ureteral catheterization techniques, Cattell and colleagues (1973) localized the site of bacteriuria in 42 patients who had follow-up for 6 months after therapy. He analyzed the response to antimicrobial therapy of 2 weeks’ duration. Of the 26 patients who were cured of their initial infection, 16 had recurrence with the same organism, 8 had upper tract infections, and 8 had bladder bacteriuria.

Most of the changes of chronic pyelonephritis seem to occur in infancy, probably because the growing kidney is most susceptible to scarring. A review that examined the long-term effect of UTIs in adults concluded that renal damage is rare in non-obstructive UTIs (Stamey, 1980), but it does occur (Bailey et al, 1969; Davies et al, 1972; Davidson and Talner, 1973; Feldberg, 1982).

The association between hypertension and the pyelonephritic kidney has been addressed by Pfau and Rosenmann (1978), who concluded that the association of chronic pyelonephritis and hypertension is usually coincidental. Their conclusion agrees with that of a study by Parker and Kunin (1973) that examined 74 women who had been admitted to the hospital 10 to 20 years previously for pyelonephritis. Only 14.5% of these women had hypertension, a rate similar to that found in a random female population of the same age.

Infectious Granulomatous Nephritis

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis (XGP) is a rare, severe, chronic renal infection typically resulting in diffuse renal destruction. Most cases are unilateral and result in a nonfunctioning, enlarged kidney associated with obstructive uropathy secondary to nephrolithiasis. XGP is characterized by accumulation of lipid-laden foamy macrophages. It begins within the pelvis and calyces and subsequently extends into and destroys renal parenchymal and adjacent tissues. It has been known to imitate virtually every other inflammatory disease of the kidney, as well as renal cell carcinoma, on radiographic examination (Malek and Elder, 1978; Tolia et al, 1980). In addition, the microscopic appearance of XGP has been confused with clear cell adenocarcinoma of the kidney on frozen section and has led to radical nephrectomy (Anhalt et al, 1971; Malek and Elder, 1978; Flynn et al, 1979; Lorentzen and Nielsen, 1980; Tolia et al, 1980). The entity is uncommon and is found in only about 0.6% (Malek et al, 1972) to 1.4% (Ghosh, 1955) of patients with renal inflammation who are evaluated pathologically.

Pathogenesis. The primary factors involved in the pathogenesis of XGP are nephrolithiasis, obstruction, and infection (Gregg et al, 1999). Nephrolithiasis has been noted in as many as 83% of the patients in various series; approximately half of the renal stones have been of the staghorn type (Parsons et al, 1983; Chuang et al, 1992; Nataluk et al, 1995). It has been proposed clinically and demonstrated experimentally that primary obstruction followed by infection with *E. coli* can lead to tissue destruction and collections of lipid material by macrophages (Povysil and Konickova, 1972). These macrophages (xanthoma cells) are distributed in sheets around parenchymal abscesses and calyces and are intermixed with lymphocytes, giant cells, and plasma cells. The bacteria appear to be of low virulence because spontaneous bacteremia has rarely been described. Other possible interrelated factors include venous occlusion and hemorrhage, abnormal lipid metabolism, lymphatic blockage, failure of antimicrobial therapy in UTI, altered immunologic competence, and renal ischemia (Friedenberg and Spjut, 1963; Mering et al, 1973; Goodman et al, 1979; McDonald, 1981; Tolia et al, 1981). The concept that XGP is related to incomplete bacterial degradation and altered host response has received mixed support (Nielsen and Lorentzen, 1981; Khalyil-Mawad et al, 1982). Thus it appears that there is probably no single factor that is instrumental in the pathogenesis of this disease. Rather, there is an inadequate host acute inflammatory response within an obstructed, ischemic, or necrotic kidney.

Pathology. The kidney is usually massively enlarged and has a normal contour. XGP may be diffuse, as in approximately 80% of the patients, or segmental. In the diffuse form of the disease, the entire kidney is involved, whereas in segmental XGP, only the parenchyma surrounding one or more calyces or one pole of a duplicated collecting system is involved. On sectioning, the kidney usually demonstrates nephrolithiasis and peripelvic fibrosis. The

calyces are dilated and filled with purulent material, but fibrosis surrounding the pelvis usually prevents dilation. The papillae are often destroyed by papillary necrosis (Goodman et al, 1979). In advanced stages of the disease, multiple parenchymal abscesses are filled with viscous pus and lined by yellowish tissue (Fig. 12-33A). The cortex is often thin and replaced by xanthogranulomatous tissue. The capsule is often thickened, and extension of the inflammatory process into the perinephric or paranephric space is common (Goodman et al, 1979; McDonald, 1981; Gregg et al, 1999).

On microscopic examination, the yellowish nodules that line the calyces and surround the parenchymal abscesses contain dark sheets of lipid-laden macrophages (foamy histiocytes with small, dark nuclei and clear cytoplasm) intermixed with lymphocytes, giant cells, and plasma cells (Fig. 12-33B). Xanthogranulomatous cells are not specific to XGP but may be present anywhere inflammation or obstruction coexists. The origin of the fatty substance is disputed. Cholesterol esters that make up a part of the lipid might be derived from lysis of erythrocytes after hemorrhage (Saeed and Fine, 1963).

Clinical Presentation. XGP should be suspected in patients with UTIs and a unilateral enlarged nonfunctioning or poorly functioning kidney with a stone or a mass lesion indistinguishable from malignant tumor. Most patients present with flank pain (69%), fever and chills (69%), and persistent bacteriuria (46%) (Malek and Elder, 1978). Additional vague symptoms, such as malaise, may be present. On physical examination, 62% of the patients had a flank mass and 35% had previous calculi (Malek and Elder, 1978). Less commonly, hypertension, hematuria, or hepatomegaly is the presenting complaint. The medical history is often positive for UTIs and urologic instrumentation (Malek and Elder, 1978; Flynn et al, 1979; Goodman et al, 1979; Grainger et al, 1982; Yazaki et al, 1982; Petronic et al, 1989; Eastham et al, 1994; Nataluk et al, 1995). Diabetics also appear to be at greater risk of

Figure 12-33. Xanthogranulomatous pyelonephritis. A, Gross specimen. Kidney is massively enlarged, measuring 23 × 12 cm; the normal architecture is replaced by a shaggy yellow upper pole mass corresponding to xanthogranulomatous inflammation and numerous distorted and dilated calyces. B, Microscopically, the shaggy yellow tissue is composed primarily of lipid-laden histiocytes mixed with other inflammatory cells. (From Schaeffer AJ. Urinary tract infections. In: Gillenwater JY, Grayhack JT, Howards SS, et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.)

developing the disease (Eastham et al, 1994). Although it may occur at any age, the peak incidence of XGP is in the fifth to the seventh decade. Women are more commonly affected than men. There is no predilection for either kidney.

Bacteriology and Laboratory Diagnosis. Although review of the literature shows *Proteus* to be the most common organism involved with XGP (Anhalt et al, 1971; Tolia et al, 1981), *E. coli* is also common. The prevalence of *Proteus* organisms may reflect their association with stone formation and subsequent chronic obstruction and irritation. Malek and Elder (1978), in their analysis of 26 cases, found that renal tissue cultures grew bacteria in 22 of 23 cases. Anaerobes also have been cultured (Malek and Elder, 1978).

Approximately 10% of patients have mixed cultures. About one third of patients have no growth in their urine, probably because many patients have recently taken or are taking antimicrobial agents when cultures are obtained. The infecting organism may be revealed only by tissue cultures obtained during surgery. Urinalysis usually shows pus and protein. In addition, blood tests often reveal anemia and may show hepatic dysfunction in up to 50% of the patients (Malek and Elder, 1978).

XGP is almost always unilateral; therefore azotemia or frank renal failure is uncommon (Goodman et al, 1979; Gregg et al, 1999).

CT is probably the most useful radiologic technique in evaluating patients with XGP (Fig. 12-34). Fifty to eighty percent of patients show the classic triad of unilateral renal enlargement with little or no function and a large calculus in the renal pelvis (Elder, 1984). CT usually demonstrates a large, reniform mass with the renal pelvis tightly surrounding a central calcification but without pelvic dilatation (Solomon et al, 1983; Goldman et al, 1984; Hartman, 1985). Renal parenchyma is replaced by multiple water-density masses representing dilated calyces and abscess cavities filled with varied amounts of pus and debris. On enhanced scans, the walls of these cavities demonstrate a prominent blush owing to the abundant vascularity within the granulation tissue. The cavities themselves, however, fail to enhance, whereas tumors and other inflammatory lesions usually do. The CT scan is particularly helpful in demonstrating the extent of renal involvement and may indicate whether adjacent organs or the abdominal wall are involved by XGP (Eastham et al, 1994; Kaplan et al, 1997).

Figure 12-34. Xanthogranulomatous pyelonephritis. Enhanced computed tomography scan shows collecting system and parenchymal calculi (straight black arrows) with lower pole pyonephrosis (curved white arrow) and an irregular, predominantly low-density perinephric abscess (A) extending into the soft tissues of the flank.

Ultrasonography usually demonstrates global enlargement of the kidney (Merenich and Popky, 1991). The normal renal architecture is replaced by multiple hypoechoic fluid-filled masses that correspond to debris-filled, dilated calyces or foci of parenchymal destruction (Fagerholm, 1983; Hartman et al, 1984). With focal involvement, a solid mass involving a segment of the kidney is demonstrated with an associated calculus in the collecting system or ureter. Renal cell carcinoma and other solid renal lesions must be considered in the differential diagnosis (Elder, 1984).

Radionuclide renal scanning using ^{99m}Tc -DMSA is used to confirm and quantify the differential lack of function in the involved kidney (Gregg et al, 1999). MRI has not yet superseded CT in the evaluation of renal inflammation, but it provides some advantages in delineating extrarenal extension of inflammation (Soler et al, 1997). Lesions of XGP may appear as cystic foci of intermediate intensity signal on T1-weighted images and hyperintensity on T2-weighted images. Arteriography shows hypovascular areas, but there may be some hypovascular areas (Malek and Elder, 1978; Van Kirk et al, 1980; Tolia et al, 1981). Therefore radiologic studies, although distinctive, often cannot be used to differentiate between XGP and renal cell carcinoma.

Differential Diagnosis. Diagnosis of segmental XGP without calculi may be difficult. XGP in association with massive pelvic dilation cannot be distinguished from pyonephrosis. When XGP occurs within a small contracted kidney, the radiographic findings are nonspecific and nondiagnostic. Renal parenchymal malacoplakia may show renal enlargement and multiple inflammatory masses replacing the normal renal parenchyma, but calculi are usually not present. Renal lymphoma may be associated with multiple hypoechoic masses surrounding the contracted, nondilated pelvis, but lymphoma is usually clinically obvious, and renal involvement is usually bilateral and not associated with calculi (Hartman, 1985).

Management. The primary obstacle to the correct treatment of XGP is incorrect diagnosis. Today with CT technology, the diagnosis of XGP is made preoperatively nearly 90% of the time (Eastham et al, 1994; Nataluk et al, 1995). Antimicrobial therapy may be necessary to stabilize the patient preoperatively, and, occasionally, long-term antimicrobial therapy will eradicate the infection and restore renal function (Mollier et al, 1995). Because the renal abnormality may be diagnosed preoperatively as a renal tumor and/or is diffuse, nephrectomy is usually performed. If localized XGP is diagnosed preoperatively or at exploration, it is amenable to partial nephrectomy (Malek and Elder, 1978; Tolia et al, 1980; Osca et al, 1997).

The lipid-laden macrophages associated with XGP, however, closely resemble clear cell adenocarcinoma and may be difficult to distinguish solely on the basis of frozen section. Furthermore, XGP has been associated with renal cell carcinoma, papillary transitional cell carcinoma of the pelvis or bladder, and infiltrating squamous cell carcinoma of the pelvis (Schoborg et al, 1980; Pitts et al, 1981; Tolia et al, 1981); thus, if malignant renal tumor cannot be excluded, nephrectomy should be performed. When diffuse and extensive disease into the retroperitoneum exists, removal of the kidney and perinephric fat may be needed. Under these circumstances, the surgery may be difficult and may involve dissection of granulomatous tissue from the diaphragm, great vessels, and bowel (Malek and Elder, 1978; Flynn et al, 1979). It is important to remove the entire inflammatory mass because in nearly three fourths of patients, xanthogranulomatous tissue is infected. If incision and drainage alone are performed rather than nephrectomy, the patient may continue to suffer from protracted debilitating illness and may develop a renal cutaneous fistula; an even more difficult nephrectomy will then be necessary. One early case-matched series of laparoscopic nephrectomies performed for XGP concluded that the benefits of laparoscopic surgery do not extend to the treatment of this disease (Bercowsky et al, 1999); however, a larger review of a modern XGP experience suggests that laparoscopic nephrectomy is a reasonable treatment approach. Some studies suggest a retroperitoneal approach laparoscopically and, if transperitoneal, the use of a

hand-assist port (Tobias-Machado et al, 2005). High conversion rates were seen across multiple studies (Korkes et al, 2008)

Malacoplakia

Malacoplakia, from the Greek word meaning “soft plaque,” is an unusual inflammatory disease that was originally described to affect the bladder but has been found to affect the genitourinary and gastrointestinal tracts, skin, lungs, bones, and mesenteric lymph nodes. It is an inflammatory lesion described originally by Michaelis and Gutmann (1902). It was characterized by von Hansemann (1903) as soft, yellow-brown plaques with granulomatous lesions in which the histiocytes contain distinct basophilic lysosomal inclusion bodies or Michaelis-Gutmann bodies. Although its exact pathogenesis is unknown, malacoplakia probably results from abnormal macrophage function in response to a bacterial infection, which is most often *E. coli*.

Pathogenesis. The pathogenesis is unknown, but several theories are popular. In 93 patients who had cultures of urine, diseased tissue, or blood, 89.4% had coliform infections (Stanton and Maxted, 1981). Moreover, 40% of the patients in this review had an immunodeficiency syndrome, autoimmune disease, carcinoma, or another systemic disorder. This association of coliform infections and compromised health status in patients with malacoplakia is well recognized.

It is hypothesized that bacteria or bacterial fragments form the nidus for the calcium phosphate crystals that laminate the Michaelis-Gutmann bodies. Most investigations into the pathogenesis of this disease support theories that a defect in intraphagosomal bacterial digestion accounts for the unusual immunologic response that causes malacoplakia.

Pathology. The diagnosis is made by biopsy. The lesion is characterized by large histiocytes, known as *von Hansemann cells*, and small basophilic, extracytoplasmic, or intracytoplasmic calculospherules called *Michaelis-Gutmann bodies*, which are pathognomonic (Fig. 12-35). Electron microscopy has revealed intact coliform bacteria and bacterial fragments within phagolysosomes of the foamy-appearing malacoplakic histiocytes (Lewin et al, 1976; Stanton and Maxted, 1981). In their review of the subject, Stanton and Maxted (1981) and Esparza and associates (1989) emphasized that, although pathognomonic for the disease, Michaelis-Gutmann bodies may be absent in early malacoplakia and are not necessary for the diagnosis.

It has been shown that macrophages in malacoplakia involving the kidney and bladder contain large amounts of immunoreactive α_1 -antitrypsin (Callea et al, 1982). The amount of α_1 -antitrypsin remains unchanged during the morphogenetic stages of the pathologic process. Macrophages from other pathologic processes, closely resembling malacoplakia but without Michaelis-Gutmann bodies, do not contain α_1 -antitrypsin except for a few macrophages in

Figure 12-35. Renal parenchymal malacoplakia. A, Cut surface demonstrates extensive cortical and upper medullary replacement by multifocal, confluent, tumorlike masses. B, Cortical surface exhibits multiple, firm, plaque-like lesions. C, Hallmark of malacoplakia is demonstration of the Michaelis-Gutmann body (arrows), which represents incompletely destroyed bacteria surrounded by lipoprotein membrane (hematoxylin and eosin stain). (From Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney: I and II. *Monogr Urol* 1985;6:3.)

tuberculosis and XGP. Therefore immunohistochemical staining for α_1 -antitrypsin may be a useful test for an early and accurate differential diagnosis of malacoplakia.

Clinical Presentation. Most patients are older than 50 years. The ratio of females to males with malacoplakia within the urinary tract is 4:1, but this disparity does not occur in other body tissues (Stanton and Maxted, 1981). The patients often are debilitated and immunosuppressed and have other chronic diseases. The symptoms of bladder malacoplakia are bladder irritability and hematuria. Cystoscopy reveals mucosal plaques or nodules. As these lesions progress, they may become fungating, firm, sessile masses that cause filling defects of the bladder, ureter, or pelvis on excretory urograms. The distal ureter may become strictured or stenotic and cause subsequent renal obstruction or nonfunction (Sexton et al, 1982). A typical patient with renal parenchymal disease may have one or more radiographic masses and chronic *E. coli* infections. Renal parenchymal malacoplakia may be complicated by renal vein thrombosis and inferior vena cava thrombosis (McClure, 1983). When malacoplakia involves the testis, epididymo-orchitis is present. Malacoplakia of the prostate is rare, but, when it occurs, it may be confused with carcinoma clinically (Shimizu et al, 1981). Mortality can exceed 50%, and the morbidity can be substantial (Stanton and Maxted, 1981).

Radiologic Findings. Multifocal malacoplakia on excretory urography typically presents as enlarged kidneys with multiple filling defects. Renal calcification, lithiasis, and hydronephrosis are absent. The multifocal nature is best appreciated by using ultrasonography, CT, or arteriography. Ultrasound examination may demonstrate renal enlargement and distortion of the central echo complex. The masses are often confluent, resulting in an overall increase in the echogenicity of the renal parenchyma (Hartman et al, 1980). On CT, the foci of malacoplakia are less dense than the surrounding enhanced parenchyma (Hartman, 1985). Arteriography typically reveals a hypovascular mass without peripheral neovascularity (Cavins and Goldstein, 1977; Trillo et al, 1977).

Unifocal malacoplakia on excretory urography appears as a noncalcified mass that is indistinguishable from other inflammatory or neoplastic lesions. Ultrasonography and CT may demonstrate a solid or cystic structure, depending on the degree of internal necrosis. Angiography may demonstrate neovascularity (Trillo et al, 1977). Extension beyond the kidney, which can occur with either multifocal or uniform malacoplakia, is best demonstrated by CT.

Differential Diagnosis. The differential diagnosis includes renal cystic disease, neoplasia, and renal inflammatory disease (Hartman, 1985). Malacoplakia should be considered when one or more renal masses are observed, particularly in female patients with recurrent UTIs with *E. coli*, altered immune response syndromes, or cystoscopic evidence of malacoplakia or filling defects in the collecting system (Charboneau, 1980). Malacoplakia should also be suspected when these radiographic findings occur in a renal transplant patient who has persistent UTI despite appropriate antimicrobial therapy. Cystic disease generally can be excluded by careful sonographic and CT evaluations. Renal involvement with metastatic disease or lymphomas usually occurs late in the course of the disease, which is well established. Multifocal renal cell carcinoma is most often seen in the context of von Hippel-Lindau disease with its other clinical manifestations. Patients with XGP usually have signs and symptoms of UTI. As with malacoplakia, the involved kidney is enlarged but renal calculi and obstruction are common. Multiple renal abscesses are often associated with hematogenous dissemination resulting from cardiac disease.

Management. Management of malacoplakia should be directed at control of the UTIs, which should stabilize the disease process. This subject is well reviewed by Stanton and Maxted (1981). Although multiple long-term antimicrobial agents, including many antituberculosis agents, have been used, the sulfonamides, rifampin, doxycycline, and TMP are thought to be especially useful because of their intracellular bactericidal activity (Maderazo et al, 1979). Fluoroquinolones are taken up by macrophages directly and have

also proven effective in the management of malacoplakia (Vallorosi et al, 1999). Other investigators have used ascorbic acid and cholinergic agents such as bethanechol in conjunction with antimicrobial therapy and have reported good results (Abdou et al, 1977; Zornow et al, 1979; Stanton et al, 1983). Both agents are thought to increase intracellular cyclic guanosine monophosphate levels, which have been postulated as the biologic defect causing macrophage dysfunction. Surgical intervention, however, may be necessary if the disease progresses in spite of antimicrobial treatment. Nephrectomy is usually performed for the treatment of symptomatic unilateral renal lesions.

The long-term prognosis appears to be related to the extent of the disease. When parenchymal renal malacoplakia is bilateral or occurs in the transplanted kidney, death usually occurs within 6 months (Bowers and Cathey, 1971; Deridder et al, 1977). Patients with unilateral disease usually have a long-term survival after nephrectomy.

Renal Echinococcosis

Echinococcosis is a parasitic infection caused by the larval stage of the tapeworm *Echinococcus granulosus*. The disease is prevalent in dogs, sheep, cattle, and humans in South Africa, Australia, New Zealand, Mediterranean countries (especially Greece), and some parts of the former Soviet Union. In the United States, the disease is rare, but it is found in immigrants from Eastern Europe or other foreign endemic areas or as an indigenous infection among American Indians in the Southwest and in Eskimos (Plorde, 1977).

Pathogenesis and Pathology. Echinococcosis is produced by the larval form of the tapeworm, which in its adult form resides in the intestine of the dog, the definitive host. The adult worm is 3 to 9 mm long. The ova in the feces of the dog contaminate grass and farmlands and are ingested by sheep, pigs, or humans, the intermediate hosts. Larvae hatch, penetrate venules in the wall of the duodenum, and are carried by the bloodstream to the liver. Those larvae that escape the liver are next filtered by the lungs. Approximately 3% of the organisms that escape entrapment in the liver and lungs may then enter the systemic circulation and infect the kidneys. The larvae undergo vesiculation, and the resultant hydatid cyst gradually develops at a rate of about 1 cm/yr. Thus the cyst may take 5 to 10 years to reach pathologic size.

Echinococcosis cysts of the kidney are usually single and located in the cortex (Nabizadeh et al, 1983). The wall of the hydatid cyst has three zones: a peripheral zone of fibroblasts derived from tissues of the host becomes the adventitia and may calcify; an intermediate laminated layer becomes hyalinized; and a single inner layer is composed of nucleated epithelium and is called the *germinal layer*. The germinal layer gives rise to brood capsules that increase in number, become vacuolated, and remain attached to the germinal membrane by a pedicle. New larvae (scolecex) develop in large numbers from the germinal layer within the brood capsule (Fig. 12-36). The hydatid cyst is also filled with fluid. When brood capsules detach, they enlarge and move freely in the fluid and are then called daughter cysts. Hydatid sand is composed of free larvae and daughter cysts.

Clinical Presentation. The symptoms of echinococcosis are those of a slowly growing tumor. Most patients are asymptomatic or have a flank mass, dull pain, or hematuria (Gilsanz et al, 1980; Nabizadeh et al, 1983). Because the cyst is focal, it rarely affects renal function. Rarely, the cyst ruptures into the collecting system, and the patient may experience severe colic and passage of debris resembling grape skins in the urine (hydatiduria). The cyst may also rupture into an adjacent viscus or the peritoneal cavity. The fluid is extremely antigenic (Hartman, 1985).

Laboratory Diagnosis. If cyst rupture occurs, the definitive diagnosis can be established by identifying daughter cysts in the urine or by identifying the laminated wall of the cyst (Sparks et al, 1976). Fewer than half of the patients have eosinophilia. The most reliable diagnostic test uses partially purified hydatid arc 5 antigens in a double-diffusion test (Coltorti and Varela-Diaz, 1978). Complement fixation, hemagglutination (HA), and the Casoni

Figure 12-36. Echinococcosis. A, Gross specimen. A cystic mass measuring 7 × 11 cm in lower pole. Smaller daughter cysts are identified within the larger cystic mass. B, Gross specimen. Daughter cysts represent brood capsules that have detached and move freely. C, Photomicrograph. Brood capsules (B) arising from the germinal layer (G) contain viable and degenerating scoleces (S). (From Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney: III and IV. *Monogr Urol* 1985;6:26.)

intradermal skin tests are less reliable but, when combined, are positive in about 90% of patients (Sparks et al, 1976).

Radiologic Findings. Excretory urography typically shows a thick-walled cystic mass, occasionally calcified (Buckley et al, 1985). If the cyst ruptures into the collecting system, daughter cysts may be outlined in the pelvis as an irregular mass or as multiple solitary lesions (Gilsanz et al, 1980). Occasionally, direct filling of the cyst with contrast medium occurs.

Ultrasonography and CT are useful in characterizing the mass. Ultrasonography usually demonstrates a multicystic or multiloculated mass. A sudden change in position may demonstrate bright falling echoes corresponding to hydatid sand, which can be observed during real-time evaluation of hydatid cysts (Saint Martin and Chiesa, 1984).

On CT, several patterns of renal echinococcosis may be recognized. The most specific is a cystic mass with discrete, round daughter cysts and a well-defined enhancing membrane (Martorana et al, 1981). The less specific pattern is that of a thick-walled multiloculated cystic mass (Gilsanz et al, 1980). The presence of daughter cysts within the mother cyst differentiates the lesion from a simple renal cyst and from renal abscesses, infected cysts, and necrotic neoplasm.

Both CT and ultrasonography are useful in evaluating the liver. Angiography is seldom required. Diagnostic aspiration should not be performed because of the danger of rupture and spillage of the highly antigenic cyst contents and risk of fatal anaphylaxis. Nevertheless, Baijal and coworkers (1995) described a percutaneous management of renal hydatidosis as a minimally invasive diagnostic and therapeutic option.

Management. The prognosis of echinococcosis is good but depends on the site and size of the cysts. Medical treatment with benzimidazole compounds such as mebendazole or albendazole has shown limited success with significant side effects (Nabizadeh et al, 1983).

Surgery remains the mainstay of treatment of renal echinococcosis (Poulios, 1991). The cyst should be removed without rupture to reduce the chance of seeding, antigen reaction, and recurrence. If the cyst wall is calcified, the larvae are probably dead and the risk of seeding is low, although a daughter cyst may be viable. If the cyst ruptures or cannot be removed and marsupialization is required, the contents of the cyst initially should be aspirated and filled

with a scolicidal agent such as 30% sodium chloride, 0.5% silver nitrate, 2% formalin, or 1% iodine for approximately 5 minutes to kill the germinal portion (Sparks et al, 1976; Nabizadeh et al, 1983; Shetty et al, 1992).

KEY POINTS: KIDNEY INFECTIONS

- Acute pyelonephritis classically presents as the abrupt onset of chills, fever, and flank or costovertebral angle tenderness but can present as symptoms as mild as cystitis or as severe as sepsis.
- Emphysematous pyelonephritis is a life-threatening infection diagnosed radiographically by the presence of gas in the parenchyma or collecting system and managed surgically.
- Renal abscesses are well delineated by CT and are classically managed with IV antimicrobial agents and drainage. Smaller abscesses may be amenable to conservative treatment with medical management.
- Pyonephrosis is a bacterial infection in a hydronephrotic kidney. Prompt diagnosis is critical; treatment entails intravenous antimicrobial agents and drainage of the obstructed renal unit.
- XGP is a chronic renal infection that is often found in poorly functioning renal units obstructed secondary to nephrolithiasis. XGP can be mistaken for renal tumors.
- Malacoplakia is an unusual inflammatory disease thought to result from abnormal macrophage function. Michaelis-Gutmann bodies are lysosomal inclusion bodies that characterize this disease microscopically.

BACTEREMIA, SEPSIS, AND SEPTIC SHOCK

Sepsis is a clinical syndrome characterized by extremes of body temperature, heart rate, respiratory rate, and WBC count that occurs in response to an infection. A detailed list of potential characteristics can be found in Box 12-9. Severe sepsis and septic shock are extensions of the sepsis spectrum and involve acute organ dysfunction and life-threatening hypotension not

BOX 12-9 Potential Characteristics of Sepsis Spectrum**GENERAL**

Fever (core temperature $>38.3^{\circ}\text{C}$)
 Hypothermia (core temperature $<36^{\circ}\text{C}$)
 Heart rate >90 min, 1 or 2 SD above the normal value for age
 Tachypnea
 Altered mental status
 Significant edema or positive fluid balance (20 mL/kg/24 hr)
 Hyperglycemia (plasma glucose >120 mg/dL or 7.7 mmol/L) in the absence of diabetes

INFLAMMATORY

Leukocytosis (WBC count $>12,000/\mu\text{L}$)
 Leukopenia (WBC count $<4000/\mu\text{L}$)
 Normal WBC count with $>10\%$ immature forms

ORGAN DYSFUNCTION

Arterial hypoxemia ($\text{PaO}_2/\text{FiO}_2 >300$)
 Acute oliguria (urine output 0.5 mL/kg in 1 hr for at least 2 hr)
 Creatinine increase of 0.5 mg/dL
 Coagulation abnormalities (INR 1.5 or aPTT >60 sec)
 Ileus (absent bowel sounds)
 Thrombocytopenia (platelet count $<100,000/\mu\text{L}$)
 Hyperbilirubinemia (plasma total bilirubin >4 mg/dL or 70 mmol/L)

TISSUE PERFUSION

Hyperlactatemia (>1 mmol/L)
 Decreased capillary refill or mottling

INR, international normalized ratio; aPTT, activated partial thromboplastin time.

From Levy MM, Fink MP, Marshall JC, et al. 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference. Crit Care Med 2003;31:1250–6.

responsive to fluid resuscitation (Dellinger et al, 2008). A typical host response to infection involves localized containment and elimination of bacteria and repair of damaged tissue. This process is facilitated by macrophages and dendritic cells and orchestrated by CD4^+ T helper cells via the release of both proinflammatory and anti-inflammatory molecules (cytokines, chemokines, interferons). Sepsis occurs when a local infectious process becomes an uncontrolled systemic blood-borne inflammatory response resulting in damage to tissues or organs remote from the initial site of infection or injury. The extremes of the spectrum are lethal in one in four patients, and there are an estimated 750,000 cases (3 cases per 1000 population) of sepsis or septic shock in the United States each year (Rivers et al, 2001; Dellinger et al, 2008). Much like other medical emergencies, including polytrauma, acute myocardial infarction, and stroke, early recognition and appropriate treatment significantly influence outcome; these are commonly known as “the golden hours.”

Definitions

- **Bacteremia:** the presence of viable bacteria in the blood
- **Systemic inflammatory response syndrome (SIRS):** a clinical syndrome characterized by the 2001 International Sepsis Definitions Conference (Levy et al, 2003) as extremes of body temperature, heart rate, ventilation, and immune response. SIRS can occur in response to multiple insults, including systemic infection, trauma, thermal injury, or a sterile inflammation.
- **Sepsis:** SIRS and infection either documented or strongly suspected
- **Severe sepsis:** sepsis plus sepsis-induced organ dysfunction or tissue hypoperfusion, typically systolic blood pressure (SBP)

less than 90 mm Hg or mean arterial pressure (MAP) less than 70 mm Hg

- **Septic shock:** an extreme form of sepsis with sepsis-induced hypotension persisting despite adequate fluid resuscitation; findings may include elevated lactic acid or oliguria

Pathophysiology

Initial studies of pathophysiologic features of septic shock concentrated on the interactions of lipopolysaccharides (LPS) from the gram-negative bacterial cell wall with various innate immune system pathways. More recent investigations now focus on understanding the activation and regulation of both the innate and acquired immune systems and the array of cytokines that are released during localized and systemic inflammatory responses.

Bacterial Cell Wall Components in Septic Shock

The exotoxins produced by some bacteria (e.g., exotoxin A produced by *P. aeruginosa*) can initiate septic shock. However, the bacteria themselves, and in particular their cell wall components, are primarily responsible for the development of septic shock. These components activate numerous innate immunologic pathways, including macrophages, neutrophils, and dendritic cells and the complement system. The prime initiator of gram-negative bacterial septic shock is endotoxin, an LPS component of the bacterial outer membrane. Endotoxin can directly activate the coagulation, complement, and fibrinolytic systems, leading to the release of small molecules that cause vasodilation and increased endothelial permeability (Tapper and Herwald, 2000).

Cytokine Network

Monocytic cells appear to have a pivotal role in mediation of the biologic effects of SIRS and septic shock. Monocytes can remove and detoxify LPS and be beneficial to the host. However, LPS-stimulated monocytes produce cytokines such as tumor necrosis factor (TNF) and interleukin (IL)-1. The intravascular activation of inflammatory systems involved in septic shock is mainly the consequence of an overproduction of these and other cytokines. Production of these cytokines is modulated by CD4^+ T helper cells. Type I CD4^+ T helper cells release proinflammatory cytokines including TNF- α , interferon- γ , and IL-2. These cytokines are also produced by macrophages, endothelial cells, and other cells stimulated by microbial products. The systemic release of large amounts of the cytokine TNF is associated with death from septic shock in humans (Waage et al, 1987; Calandra et al, 1988; Girardin et al, 1988). However, despite the fact that TNF is classically regarded as a central mediator of pathophysiologic changes associated with sepsis, the role of attenuation of this and other proinflammatory cytokines remains unclear. For example, in one animal model of peritonitis, survival was worsened by the administration of antibodies blocking TNF (Eskandari et al, 1992). Also, patients suffering from rheumatoid arthritis treated with TNF- α agents remain susceptible to the development of septic shock. Lastly, a meta-analysis of clinical trials utilizing anti-inflammatory agents in sepsis suggested these agents were generally harmful in all but a small subset of patients (Hotchkiss and Karl, 2003). More recently, anti-inflammatory cytokines, including IL-4 and IL-10, released by type II CD4^+ T helper cells, have also been noted to be elevated in sepsis, further illustrating the complex regulation of both proinflammatory and anti-inflammatory cytokines in a septic patient. In summary, both proinflammatory and anti-inflammatory cytokines are elements of early sepsis; however, the role of cytokine modulation in the treatment of sepsis remains unclear.

Clinical Presentation and Diagnosis

Early signs of systemic inflammatory response syndrome include temperature extremes ($>38^{\circ}\text{C}$ [100.4°F] or $<36^{\circ}\text{C}$ [96.8°F]), tachycardia (heart rate >90 beats/min), tachypnea, and altered

mental status. The classic bedside findings differentiating septic shock from other types of shock include a warm patient, brisk capillary refill, and a bounding pulse reflecting pyrexia, peripheral vasodilation, and decreased systemic vascular resistance. Other diagnostic criteria include evidence of organ dysfunction such as hypotension, oliguria, or ileus and laboratory abnormalities including leukocytosis or leukopenia, hyperbilirubinemia, hyperlactatemia, hyperglycemia, coagulation abnormalities, and elevated C-reactive protein and procalcitonin (see Box 12-9). The classic clinical presentation of fever and chills followed by hypotension is manifest only in about 30% of patients with gram-negative bacteremia (McClure, 1983). Even before temperature extremes and the onset of chills, bacteremic patients often begin to hyperventilate. Thus the earliest metabolic change in septicemia is a resultant respiratory alkalosis. In critically ill patients, the sudden onset of hyperventilation should lead to blood drawing for culture and careful evaluation of the patient. Changes in mental status can also be important clinical clues. Although the most common pattern is lethargy or obtundation, an occasional patient may become excited, agitated, or combative. Cutaneous manifestations such as the bull's-eye lesion associated with *P. aeruginosa* may be identified.

Metastatic infections secondary to genitourinary tract bacteremia have been described (Siroky et al, 1976). In this review of 137 patients who developed metastatic infections from bacteremia with a genitourinary source, 79% had undergone prior urologic instrumentation, 59% developed skeletal infections, mainly of the spine, and 29% developed endocarditis, most commonly caused by *E. faecalis*.

Bacteriology

In classic studies of sepsis syndrome and septic shock, gram-negative bacteria were predominant organisms isolated in 30% to 80% of cases and gram-positive bacteria in 5% to 24% (Ispahani et al, 1987; Calandra et al, 1988; Bone, 1991). Although *E. coli* is the most common organism causing gram-negative bacteremia, many nosocomial catheter-associated infections are caused by highly resistant gram-negative organisms: *P. aeruginosa*, *Proteus*, *Providencia*, and *Serratia*. *Acinetobacter* and *Enterobacter* are also emerging as important nosocomial pathogens. In a large series, *E. coli* caused about one third of the cases; the *Klebsiella-Enterobacter-Serratia* family, approximately 20%; and *Pseudomonas*, *Proteus*, *Providencia*, and anaerobic species, approximately 10% each (Kreger et al, 1980). Anaerobic organisms may cause bacteremia when the source is a postsurgical intra-abdominal abscess or transrectal prostatic biopsy. More recent studies suggest the incidence of sepsis caused by both gram-positive bacterial and fungal organisms is increasing (Martin et al, 2003) and reinforce the need for initial broad-spectrum antimicrobial coverage.

Management

The principles of management of sepsis include resuscitation, supportive care, monitoring, administration of broad-spectrum antimicrobial agents, and drainage or elimination of infection (Sessler et al, 2004; Dellinger et al, 2008). Although the identification and early intervention of sepsis by the urologist is important, the use of expert consultants is also recommended because management of sepsis and the critically ill patient is complex and always evolving. Early goal-directed therapy remains the standard approach since it was shown to be significantly beneficial in a 263-patient study by Rivers and colleagues in 2001.

Principles of resuscitation include support of the airway and breathing and optimization of perfusion with the use of invasive pressure monitoring with central access (Rivers et al, 2001). Intubation and mechanical ventilation may be required in patients who are obtunded and unable to protect their airway. Supplemental oxygen may be instituted, but supranormal oxygen delivery is no longer considered a goal of therapy (Dellinger et al, 2008). Tissue perfusion should first be optimized with fluid resuscitation to

restore mean circulating filling pressures; this may include both crystalloid and or colloid/blood products. If additional blood pressure support is needed, vasoactive agents including phenylephrine, norepinephrine, vasopressin, and dopamine can be instituted; however, low-dose dopamine administration for renal protection is no longer recommended by critical care experts. Other principles of resuscitation and supportive care include optimization of oxygen delivery, correction of coagulopathies if clinically significant, maintenance of blood glucose levels below 110 mg/dL with intensive insulin therapy (Van den Bergh et al, 2001), and implementation of hemofiltration as needed (Schiffl et al, 2002). The use of hydrocortisone therapy in septic shock patients did not show a survival or disease-specific benefit in patients in a large study (Sprung et al, 2008).

Identification of the presumptive source of infection and cultures from corresponding fluids and blood should be obtained before the initiation of antimicrobial therapy. Multiple blood cultures for aerobic and anaerobic organisms should be obtained. In addition, all potential sources of bacteremia must be cultured (i.e., urine, sputum, and wounds). Careful attempts to identify the source of infection should be made because the choice of appropriate antimicrobial coverage depends on the organisms that are thought most likely to cause the infection. The severity of the underlying disease and the possibility of synergistic interactions are also important considerations. If the urinary tract is the most likely portal of entry, a broad spectrum antimicrobial either alone or in combination with an aminoglycoside should be administered. Three clinical factors have been predictive of the subsequent isolation of a resistant pathogen: (1) the use of an antimicrobial drug in the last month, (2) advanced age, and (3) male sex (Leibovici et al, 1992). If the infection is hospital acquired, or if the patient has had multiple infections or is immunocompromised or severely ill, an aminoglycoside and anti-*Pseudomonas* β -lactam or a third-generation cephalosporin should be used. When identification and drug susceptibilities of the offending organism are known, antimicrobial therapy should be changed to use the lowest cost, least toxic antimicrobial with the narrowest antimicrobial coverage. Antimicrobial treatment should be continued until the patient has been afebrile for 3 to 4 days and is clinically stable. Local infections that may have provided the focus for the bacteremia should be treated individually as appropriate. The surviving sepsis campaign suggests the initiation of broad-spectrum antibiotics within 1 hour of diagnosis of septic shock (Dellinger et al, 2008).

KEY POINTS: BACTEREMIA, SEPSIS, AND SEPTIC SHOCK

- Sepsis is a clinical syndrome characterized by extremes of body temperature, heart rate, respiratory rate, and WBC count that occurs in response to an infection.
- The principles of management of sepsis include resuscitation, supportive care, monitoring, administration of broad-spectrum antimicrobial agents, and drainage or elimination of infection.
- The surviving sepsis campaign and early goal-directed therapy has been shown to improve outcomes in critically ill patients.

BACTERIURIA IN PREGNANCY

Asymptomatic bacteriuria is one of the most common infectious issues encountered during pregnancy. The prevalence of asymptomatic bacteriuria does not change with the occurrence of pregnancy and ranges from 2% to 7% (Hooton et al, 2000). The risk of acquiring bacteriuria during pregnancy increases with lower socioeconomic class, multiparity, and sickle cell traits (Patterson and Andriole, 1987; Stenqvist et al, 1989).

The site of bacteriuria in pregnant female patients probably also reflects the situation before conception. In two studies that localized the origin of the bacteriuria, one using the Stamey ureteral catheterization technique and the other the Fairley bladder washout, upper tract infections were found in 44% and 24.5% of pregnant female patients, respectively (Fairley et al, 1966; Heineman and Lee, 1973). In nonpregnant females with recurrent bacteriuria, Stamey (1980) has reported about a 50% probability that the origin is in the upper tract. With other techniques, which may reflect the severity of tissue infection rather than the location of infection, the results are similar; approximately 50% of women with screening bacteriuria of pregnancy are fluorescent antibody-positive (Fa⁺) and thus have evidence of upper tract infection (Harris et al, 1976). Fairley and his group (1973) found that the site of infection is unrelated to the likelihood that pyelonephritis will develop during pregnancy.

Spontaneous resolution of bacteriuria in pregnant women is unlikely unless treated. Nonpregnant patients often clear their asymptomatic bacteriuria (Hooton et al, 2000), but pregnant women become symptomatic more frequently and tend to remain bacteriuric (Elder et al, 1971).

Pyelonephritis develops in 1% to 4% of all pregnant women (Sweet, 1977) and in 20% to 40% of pregnant women with untreated bacteriuria (Pedler and Bint, 1987; Wright et al, 1993). Of the women who develop pyelonephritis during pregnancy, 60% to 75% acquire it during the third trimester (Cunningham et al, 1973), when hydronephrosis and stasis in the urinary tract are most pronounced. From 10% to 20% of pregnant women who get pyelonephritis develop it again before or just after the delivery (Cunningham et al, 1973; Gilstrap et al, 1981). Moreover, a third of pregnant women who develop pyelonephritis have a documented prior history of pyelonephritis (Gilstrap et al, 1981).

The increased likelihood that bacteriuria may progress to acute pyelonephritis during pregnancy alters the morbidity of bacteriuria for this group. Treatment of screening bacteriuria of pregnancy decreases the incidence of acute pyelonephritis during pregnancy from a range of 13.5% to 65% to a range of 0% to 5.3% (Sweet, 1977).

Pathogenesis

The anatomic and physiologic changes induced by the gravid state significantly alter the natural history of bacteriuria (Patterson and Andriole, 1987). These changes may cause pregnant women to be more susceptible to pyelonephritis and may require alteration of therapy. These changes have been well summarized in several reviews (Davidson and Talner, 1978; Waltzer, 1981).

Anatomic and Physiologic Changes during Pregnancy

Increase in Renal Size

Renal length increases approximately 1 cm during normal pregnancy. It is thought that this does not represent true hypertrophy but is the result of increased renal vascular and interstitial volume. No histologic changes have been identified in renal biopsies (Waltzer, 1981).

Smooth Muscle Atony of the Collecting System and Bladder

The collecting system, especially the ureters, undergoes decreased peristalsis during pregnancy, and most women in their third trimester show significant ureteral dilatation (Davison and Lindheimer, 1978; Kincaid-Smith, 1978; Waltzer, 1981) (Fig. 12-37).

Figure 12-37. Progressive hydroureter and hydronephrosis observed on intravenous pyelogram during a normal pregnancy. A, 15 weeks; B, 18 weeks; C, 22 weeks; D, 26 weeks; E, 34 weeks; F, 39 weeks; G, 1 week postpartum; H, 6 weeks postpartum. Bilateral hydroureter and hydronephrosis are shown as early as 15 weeks (A). B to H, Successive urograms are from one patient during a normal pregnancy. Dilation occurs mainly on the right side, and both urinary tracts are normal by 6 weeks after delivery. (From Hundley JM, Walton HJ, Hibbits JT, et al. Physiologic changes occurring in the urinary tract during pregnancy. *Am J Obstet Gynecol* 1935;30:625-49.)

This hydroureter has been attributed both to the muscle-relaxing effects of increased progesterone during pregnancy and to mechanical obstruction of the ureters by the enlarging uterus at the pelvic brim. Progesterone-induced smooth muscle relaxation also may cause an increased bladder capacity (Waltzer, 1981). Later in pregnancy, the dilation may be the result of the obstructive effect of the enlarging uterus (Poole and Thorsen, 1999).

Bladder Changes

The enlarging uterus displaces the bladder superiorly and anteriorly. The bladder becomes hyperemic and may appear congested endoscopically (Waltzer, 1981). Estrogen stimulation probably causes bladder hypertrophy, as well as squamous changes of the urethra (Waltzer, 1981).

Augmented Renal Function

The transient increases in glomerular filtration rate and renal plasma flow during pregnancy have been well summarized by several authors and are probably secondary to the increase in cardiac output (Zacur and Mitch, 1977; Davison and Lindheimer, 1978; Kincaid-Smith, 1978; Waltzer, 1981). Glomerular filtration increases by 30% to 50%, and urinary protein excretion increases. The significance of these physiologic changes is apparent when the normal serum creatinine and urea nitrogen values for pregnant women are surveyed (Table 12-16). Values considered normal in nonpregnant women may represent renal insufficiency during pregnancy.

Davison and Lindheimer (1978) recommend that pregnant patients with serum creatinine levels greater than 0.8 mg/dL or urea nitrogen levels greater than 13 mg/dL undergo further evaluation of renal function. Similarly, urinary protein in pregnancy is not considered abnormal until greater than 300 mg of protein in 24 hours is excreted.

These significant physiologic changes in pregnancy, which may develop as early as the first trimester, lead to urinary stasis and mild hydroureteronephrosis and contribute to development of pyelonephritis.

Recent studies of *E. coli* adhesins and their respective specific tissue receptors have established an adhesin-based mechanism of pyelonephritis-induced preterm births and low birth weights in mice (Kaul et al, 1999). There is a higher incidence of *E. coli*-bearing Dr adhesins during the third trimester of pregnancy in women with gestational pyelonephritis (Nowicki et al, 1994) and an upregulation of Dr adhesin in the kidney, endometrium, and placenta during the third trimester of pregnancy (Martens et al, 1993). When infected intravesically with *E. coli*-bearing Dr adhesin, nearly 90% of mice that were hypo-responsive to bacterial lipopolysaccharide and had a deficient immune response delivered preterm, compared with 10% of mice infected with *E. coli* without Dr adhesin. Also, there was a significant reduction in fetal birth weight in the Dr adhesin-infected group. Bacterial tissue culture showed systemic spread of the *E. coli*-bearing Dr adhesins to the placentae and fetuses.

TABLE 12-16 Average Values for Serum Creatinine and Urea Nitrogen

	NONPREGNANT FEMALES (mg/dL)	PREGNANT FEMALES (mg/dL)
Serum creatinine	0.7	0.5
Urea nitrogen	13.0	9.0

Data from Davison JM, Lindheimer MD. Renal disease in pregnant women. Clin Obstet Gynecol 1978;21:411.

Complications Associated with Bacteriuria during Pregnancy

Prematurity and Prenatal Mortality

In the preantimicrobial era, pregnant women with symptomatic UTIs and bacterial pyelonephritis were reported to have a high incidence of prematurity, low birth weight, and death (Gilstrap et al, 1981). The relationship between asymptomatic bacteriuria and prematurity is less clear. Gilstrap and colleagues (1981) found no difference in pregnancy among patients treated for asymptomatic bacteriuria as compared with nonbacteriuric controls. However, Cunningham's review suggests that ascending GU tract infections may contribute to up to 50% of premature deliveries, especially before 30 weeks' gestation (Cunningham et al, 2013). Because women with asymptomatic bacteriuria are at higher risk for developing a symptomatic UTI that results in adverse fetal sequelae, complications associated with bacteriuria during pregnancy and pyelonephritis and its possible sequelae such as sepsis in the mother, all women with asymptomatic bacteriuria should be treated (Smail, 2001).

Maternal Anemia

Although several studies suggest that bacteriuria untreated during pregnancy is associated with maternal anemia, not all studies support this. Some difficulties in interpreting the results of these surveys have been caused by inadequate documentation of bacteriuria. In one survey in which urine cultures were obtained by suprapubic aspiration, the data suggest that pregnant patients requiring three or more treatments for bacteriuria have lower levels of serum hemoglobin and folate than controls (McFadyen et al, 1973). In another study from England, investigators showed a statistically significant difference in the incidence of anemia between 410 bacteriuric pregnant women and 409 control pregnant women (Williams et al, 1973). In this survey, 14.6% of bacteriuric women and 10% of control women were anemic at the first prenatal visit. This separation increased during the third trimester (32 weeks), when 25% of women treated with placebo alone had anemia, but only 16.8% of those women treated with antimicrobial agents had anemia. Furthermore, in the 31 untreated (placebo-treated) bacteriuric women who subsequently developed pyelonephritis, the incidence of anemia was 45.2%. These investigators concluded that "untreated bacteriuria increases the likelihood of developing anemia during pregnancy and that this risk is enhanced by the development of acute pyelonephritis, even if it is treated promptly."

Laboratory Diagnosis

Significant false-negative rates occur if screening is conducted by urinalysis or reagent strip testing (McNair et al, 2000; Preston et al, 1999). Therefore an initial screening culture should be performed in all pregnant women during the first trimester (Stenqvist et al, 1989). If the culture shows no growth, repeat cultures are generally unnecessary because patients who have no growth in their urine early in their pregnancy are unlikely to develop bacteriuria later (Norden and Kass, 1968; McFadyen et al, 1973). Pregnant women with a history of recurrent UTI or vesicoureteral reflux may benefit from antimicrobial prophylaxis (Bukowski et al, 1998).

Management

Selection of an antimicrobial agent to treat the bacteriuria must be made, however, with special considerations given to maternal and fetal toxicity. The physiologic changes of pregnancy may decrease tissue and serum drug concentrations. Maternal expanded fluid volume, the distribution of the drug in the fetus, increased renal blood flow, and increased glomerular filtration decrease the serum drug concentration. If the culture is positive, special consideration must be given to the selection of antimicrobial agents

TABLE 12-17 Oral Antimicrobial Agents Used in Pregnancy

DRUG	DOSAGE	COMMENTS
AGENTS CONSIDERED SAFE		
Penicillins		
Ampicillin	500 mg qid	Extensively used
Amoxicillin	250 mg tid	Safe and effective
Penicillin V	500 mg qid	Used less frequently but achieves excellent urinary levels
Cephalosporins		
Cephalexin	500 mg qid	Extensively used
Cefaclor	500 mg qid	Somewhat more effective against gram-negative organisms
Nitrofurantoin	100 mg qid	May be used during the first two trimesters; may result in hemolytic anemia in patients with G6PD deficiency
AGENTS THAT SHOULD BE AVOIDED		
Fluoroquinolones		Possible damage to immature cartilage
Chloramphenicol		Associated with “gray baby” syndrome
Trimethoprim		May cause megaloblastic anemia because of anti-folic acid action
Erythromycin		Associated with maternal cholestatic jaundice
Tetracyclines		May cause acute liver decompensation in the mother and inhibition of new bone growth in the fetus

G6PD, glucose-6-phosphate dehydrogenase.

Modified from Schaeffer AJ. Urinary tract infections. In: Gillenwater JY, Grayhack JT, Howards SS, et al, editors. Adult and pediatric urology. Philadelphia: Lippincott Williams & Wilkins; 2002. p. 211–72.

chosen to treat infection to prevent fetal toxicity. The pathogens are similar to those seen in nonpregnant women (MacDonald et al, 1983). Table 12-17 lists the antimicrobial agents and dosing for use in pregnancy. The aminopenicillins and cephalosporins are considered safe and generally effective throughout pregnancy. In patients with penicillin allergy, nitrofurantoin is a reasonable alternative. It may be used safely during the first two trimesters in patients without glucose-6-phosphate dehydrogenase deficiency. Given the low efficacy of short-course β -lactam therapy in nonpregnant women, it is prudent to prescribe a full 3- to 7-day course of therapy in pregnant women. A recent Cochrane Review completed by Widmer and colleagues suggests that there is not adequate evidence at this time to suggest a single dose treatment to be noninferior to standard 7-day treatment (Widmer et al, 2011). Follow-up cultures should be obtained to document absence of infection. If the culture is positive, the cause of bacteriuria must be determined to be lack of resolution, bacterial persistence, or reinfection. If the infection is unresolved, proper selection and administration of another drug probably will solve the problem. If the problem is bacterial persistence or rapid reinfection, antimicrobial suppression of infection or prophylaxis (Pfau and Sacks, 1992) throughout the remainder of the pregnancy should be considered.

Pregnant women with acute pyelonephritis should be hospitalized and treated initially with parenteral antimicrobial agents. More than 95% of these patients respond within 24 hours using ampicillin and an aminoglycoside (Cunningham et al, 1973) or cephalosporins (Sanchez-Ramos et al, 1995). Appropriate oral agents should then be given for at least 14 days (Faro et al, 1984). After the treatment course is completed, low-dose prophylaxis with nitrofurantoin, amoxicillin, or cephalexin has been shown to be effective in preventing reinfection (Van Dorsten et al, 1987; Sandberg and Brorson, 1991). The efficacy of postcoital prophylaxis with either cephalexin (250 mg) or nitrofurantoin (50 mg) has been reported (Pfau and Sacks, 1992).

Drugs that are relatively contraindicated during pregnancy include the fluoroquinolones, TMP, chloramphenicol, erythromycin, tetracycline, sulfonamides, and sometimes nitrofurantoin (Nicolle, 1987). Fluoroquinolones are contraindicated because of their effects on immature cartilage. TMP may have teratogenic effects and should be avoided, especially in the first trimester. The “gray baby” syndrome is a toxic effect of chloramphenicol

on neonates resulting from the inability of the infant to metabolize or excrete the drug. Erythromycin may cause cholestatic jaundice in the mother. Tetracycline may cause fetal malformations and maternal liver decompensation. Sulfonamides may cause kernicterus and neonatal hyperbilirubinemia and should be avoided in the third trimester. As mentioned above, nitrofurantoin can cause hemolytic anemia in both mother and child when glucose-6-phosphate dehydrogenase deficiency is present (Nicolle, 1987).

Pregnancy in Women with Renal Insufficiency

With current management of recurrent UTIs, infections alone are no contraindication to pregnancy. In patients who have renal insufficiency with or without UTIs, Davison and Lindheimer (1978) emphasize that renal function should be carefully evaluated by both serum creatinine levels and creatinine clearance before a woman is counseled about conceiving or continuing a pregnancy. Although little is known about the outcome of pregnancies with differing degrees of renal insufficiency, it is known that normal pregnancy is rare if the preconception serum creatinine level exceeds 3 mg/dL (about 30 mL/min clearance).

The degree of renal function impairment is the major determinant for pregnancy outcome. The fetal survivors of pregnant women with mild or moderate renal disease (serum creatinine <1.4 mg/dL and from 1.4 mg/dL to 2.4 to 2.8 mg/dL, respectively) is only slightly diminished, and irreversible deterioration of maternal renal function is uncommon. However, the perinatal mortality is approximately four times higher with severe disease. The rate of perinatal morbidity caused by low birth weight or prematurity doubles from mild to moderate renal disease and again from moderate to severe disease (Vidaeff et al, 2008).

BACTERIURIA IN THE ELDERLY

UTIs in the elderly are a common and expanding health problem (Kaye, 1980). In 2003, there were almost 34 million Americans older than 65 years (U.S. Census Bureau, 2003). As the life expectancy increases, the diagnosis, treatment, morbidity, and mortality of UTIs in the elderly will assume increasing importance.

KEY POINTS: BACTERIURIA IN PREGNANCY

- Screening for bacteriuria with a culture should be performed in all pregnant women during the first trimester.
- The prevalence of bacteriuria does not change with the occurrence of pregnancy; however, unlike in nonpregnant women, spontaneous resolution of bacteriuria in pregnant women is unlikely.
- All pregnant women with bacteriuria should be treated.
- Bacteriuria more commonly progresses to acute pyelonephritis during pregnancy.
- Pyelonephritis develops in 1% to 4% of all pregnant women (Sweet, 1977) and in 20% to 40% of pregnant women with untreated bacteriuria.
- Pregnant women with acute pyelonephritis should be hospitalized and treated initially with parenteral antimicrobial agents.

Epidemiology

At least 20% of women and 10% of men older than 65 years have bacteriuria (Boscia and Kaye, 1987). In contrast to young adults, in whom bacteriuria is 30 times more prevalent in women than in men, the ratio in women to men with bacteriuria progressively decreases to 2 : 1. Most elderly patients with bacteriuria are asymptomatic; estimates among women living in nursing homes range from 17% to 55%, as compared with 15% to 31% for their male cohorts (Nicolle, 1994). The prevalence of bacteriuria in the elderly increases with age (Table 12-18) (Sourander, 1966; Brocklehurst et al, 1968) and concurrent disease (Fig. 12-38) and may exceed 50% in selective groups (Boscia and Kaye, 1987; Schaeffer, 1991). Risk factors can be compounded. In a study of 373 women and 150 men older than 68 years, 24% of functionally impaired nursing home residents had bacteriuria compared with 12% of healthy domiciliary subjects (Boscia et al, 1986). Longitudinal studies have clarified the dynamic aspect of bacteriuria in the elderly with frequent, spontaneous alteration between positive and negative urine cultures (Monane et al, 1995) (Fig. 12-39). There is only a small pool of elderly patients with persistent bacteriuria (Kaye, 1980). The incidence of asymptomatic bacteriuria is much more common than is apparent from a single survey, implying that most elderly will eventually have episodes of bacteriuria (Boscia et al, 1986).

Pathogenesis

The pathophysiology of increased susceptibility is multifactorial and poorly understood. Age-related changes include decline

in cell-mediated immunity, neurogenic bladder dysfunction, increased perineal soiling as a result of fecal and urinary incontinence, increased incidence of urethral catheter placement, and, in women, changes in the vaginal environment associated with estrogen depletion (Schaeffer, 1991; Raz and Stamm, 1993). Increased receptivity of uroepithelial cells (Reid et al, 1984) and a decrease in prostatic and vaginal antimicrobial factors associated with changes in pH and levels of zinc and hormones have been observed (Boscia et al, 1986). Bacteriologic characteristics of infection in the elderly differ from those in younger patients (Baldassarre and Kaye, 1991). *E. coli* remains the most common uropathogen, causing 75% of these infections. There is a significant increase in the incidence of *Proteus*, *Klebsiella*, *Enterobacter*, *Serratia*, and *Pseudomonas* species, as well as enterococci. Bacteriuria caused by gram-positive bacteria is much more common in elderly men than in elderly women (Jackson et al, 1962). *S. saprophyticus* is not seen in this population. Polymicrobial bacteriuria is more common among the elderly (Nicolle et al, 1987). The shift in the pattern of uropathogens, the high frequency of polymicrobial infections, and antimicrobial resistance in UTIs in the elderly are due in large part to the high frequency of institutionalization and hospitalization, catheterization, and antimicrobial usage in this population (Fig. 12-40).

Laboratory Diagnosis

Diagnosis of bacteriuria and UTIs in the elderly can be difficult. Urinary tract symptoms are often absent, and concomitant disease can mask or mimic UTI. Even severe upper tract infections may not be associated with fever or leukocytosis (Baldassarre and Kaye, 1991). Therefore a high index of suspicion is warranted, and diagnosis should rely on the results of a carefully obtained urinalysis and culture. The presence of greater than 10^5 cfu/mL of urine remains the standard for diagnosis in these patients. However, counts of 10^2 or more bacteria are clinically

TABLE 12-18 Bacteriuria in Two Population Surveys

AGE (yr)	MEN (%)	WOMEN (%)
65-70	2-3	20-21
>80	21-22	23-50

Figure 12-38. Frequency of significant bacteriuria related to underlying disease. (Modified from Jackson GG, Arana-Sialer JA, Andersen BR, et al. Profiles of pyelonephritis. *Arch Intern Med* 1962;110:63-75.)

significant in catheterized specimens (Kunin, 1987; Nicolle et al, 2005).

Pyuria alone is not a good predictor or an indication for antimicrobial treatment of bacteriuria in this population (Ouslander et al, 1996; Nicolle et al, 2005). Boscia and associates (1989) reported that more than 60% of women with pyuria of 10 WBCs/mm³ or greater (noted in midstream specimens) did not have a concurrent bacteriuria. However, the absence of pyuria was a good predictor of the absence of bacteriuria.

Because urinary tract abnormalities can often predispose and complicate bacteriuria in the elderly, a thorough urologic evaluation is warranted. Renal dysfunction, calculi, hydronephrosis, urinary retention, neurogenic bladder dysfunction, and other abnormalities should be identified by serum creatinine measurement, excretory urography, CT, ultrasonography, urodynamics, and/or cystoscopy. The timing and sequence of these tests should be dictated by the clinical setting.

Significance of Screening Bacteriuria

Screening for asymptomatic bacteriuria in elderly residents in the community or long-term care facilities is not recommended (Nicolle et al, 1983; Nordenstam et al, 1986; Boscia et al, 1987; Abrutyn et al, 1994). There is no documented relationship between asymptomatic bacteriuria and uncomplicated UTIs and worsening renal function in this population. The treatment of asymptomatic bacteriuria to improve incontinence has not been justified (Baldassarre and Kaye, 1991; Ouslander et al, 1995). Although studies have demonstrated decreased survival in bacteriuric patients compared with nonbacteriuric control subjects, it is unclear whether increased mortality rates and bacteriuria are causally related (Baldassarre and Kaye, 1991; Abrutyn et al, 1994).

Studies that have found a significantly increased mortality among persons with bacteriuria have looked at populations that were heterogeneous in terms of age and underlying disease (Dontas et al, 1981; Latham et al, 1985). An age difference of only 2 years increases mortality by 20% (Dontas et al, 1968). Therefore, in the studies mentioned previously (Dontas et al, 1968) and others (Abrutyn et al, 1994), it is not clear how much of the observed association between bacteriuria and mortality was due to differences in age between the bacteriuric and the abacteriuric groups. In a study of bacteriuria and mortality in a homogeneous 70-year-old population, the association between bacteriuria and mortality was weaker and linked to fatal diseases not attributable to bacteriuria (Dontas et al, 1968). Nicolle and associates (1987) randomized institutionalized women with bacteriuria to treatment or observation and followed these patients for more than 1 year. Treatment did not result in improved survival and was associated with a number of adverse effects.

Bacteriuria that leads to UTIs in elderly subjects in the presence of underlying structural urinary tract abnormalities (e.g., obstruction with hydronephrosis) or systemic conditions (e.g., severe diabetes mellitus) are clinically significant, can lead to renal failure, and require prompt therapy. In addition, UTIs caused by urea-splitting bacteria, such as *Proteus* or *Klebsiella* species that cause formation of infection stones, may also lead to severe renal damage.

Sepsis and its sequelae (sepsis syndrome and septic shock) are increasingly common in the elderly. This is in part due to the

aggressive use of catheters (Kunin et al, 1992) and other invasive equipment, implantation of prosthetic devices, and the administration of chemotherapy to cancer patients or corticosteroids in other immunosuppressed patients with organ transplants or inflammatory diseases. In addition, modern medical care has given longer life spans to the elderly and patients with metabolic, neoplastic, or immunodeficiency disorders, who remain at increased risk for infection.

Management

Prospective randomized comparative trials of antimicrobial or no therapy in elderly male and female nursing home residents with asymptomatic bacteriuria consistently document no benefit of antimicrobial therapy. There was no decrease in symptomatic episodes and no improvement in survival. In fact, treatment with antimicrobial therapy increases the occurrence of adverse drug effects and reinfection with resistant organisms and increases the cost of treatment. Therefore asymptomatic bacteriuria in elderly residents of long-term care facilities should not be treated with antimicrobial agents.

If patients present with lower tract symptoms, 7 days of therapy is recommended. For individuals presenting with fever or more severe systemic infection 10 to 14 days of therapy is recommended. The goal in this population is to eliminate symptoms but not sterilize the urine (McMurdo and Gillespie, 2000).

The 10% to 15% decrease in susceptibility of uropathogens to β -lactams, TMP-SMX, and fluoroquinolones in isolates from nursing home residents is disturbing and most likely due to a pattern of empirical prescribing in the nursing homes. In contrast, the susceptibility of isolates from patients with acute uncomplicated UTI in an outpatient setting has not changed appreciably in 10 years. The difference in susceptibility between the isolates from the outpatient and nursing home settings can be attributed to the presence of additional risk factors for antimicrobial resistance in the latter group. These risk factors include frequent antimicrobial usage, overcrowding, underlying pathology, and the presence of catheters and other invasive devices. Antimicrobial use needs to be guided by current surveillance studies of targeted uropathogenic bacteria and implemented (Vromen et al, 1999).

The elderly population is more susceptible than young patients to the toxic and adverse effects of antimicrobial agents (Grieco, 1980; Carty et al, 1981; Boscia et al, 1986) because the metabolism and excretion of antimicrobial agents may be impaired, and the resulting increased serum levels can further damage renal function. Interactions with other medications can occur (Stahlmann and Lode, 2003). The safety margin between therapeutic and toxic doses is significantly narrowed. Therefore antimicrobial agents must be used judiciously, and dosing and drug levels should be carefully monitored.

The fluoroquinolones are effective in this population, and the side effects are not more apparent than in a younger population. However, fluoroquinolones can cause QT interval prolongation, and therefore they should be avoided in patients with known prolongation of the QT interval, patients with uncorrected hypokalemia or hypomagnesemia, and patients receiving some antiarrhythmic agents (Stahlmann and Lode, 2003).

Chondrotoxicity of fluoroquinolones has led to restricted use in pediatric patients, but there is no indication that similar effects could occur in joint cartilage of adults. Tendinitis and tendon ruptures have occurred in rare cases. Chronic renal diseases, concomitant use of corticosteroids, and age older than 60 years have been recognized as risk factors for fluoroquinolone-induced tendon disorders (Stahlmann and Lode, 2003).

CATHETER-ASSOCIATED BACTERIURIA

Catheter-associated bacteriuria is the most common hospital-acquired infection, accounting for up to 40% of such infections and more than 1 million per year (Haley et al, 1985; Stamm,

KEY POINTS: BACTERIURIA IN THE ELDERLY

- Bacteriuria is very common in both elderly women and men.
- Screening for bacteriuria is not recommended in elderly patients because there is no relationship between asymptomatic bacteriuria and uncomplicated UTIs and deteriorating renal function; asymptomatic bacteriuria should not be treated.
- Infections of the urinary tract may present as subtle signs, and a high index of suspicion is often required for diagnosis.
- Treatment of symptomatic UTI requires modifications for physiologic and pathophysiologic conditions of the elderly.

1991). The development of bacteriuria in the presence of an indwelling catheter is inevitable and occurs at an incidence of approximately 10% per day of catheterization. Sterile and clean intermittent catheterization has been associated with rates of bacteriuria ranging from 1% to 3% per catheterization (Warren, 1997). The most important risk factors associated with increased likelihood of developing catheter-associated bacteriuria are duration of catheterization, female gender, absence of systemic antimicrobial agents, and catheter-care violations (Stamm, 1991). Most catheter-associated UTIs are asymptomatic. In patients with short-term catheter placement, only 10% to 30% of bacteriuric episodes produce typical symptoms of acute infection (Haley et al, 1981; Hartstein et al, 1981). Similarly, although patients with long-term catheters are bacteriuric, the incidence of febrile episodes occurs at a rate of only 1 per 100 days of catheterization (Warren, 1991). The financial impact of community-acquired UTIs is nearly \$1.6 billion in the United States alone (Foxman, 2002); the annual cost of nosocomial UTIs has been estimated to range from between \$515 million and \$548 million (Jarvis, 1996). Each catheter-associated urinary tract infection (CAUTI) is estimated to cost between \$589 and \$758 (Tambyah et al 2002; Anderson et al 2007). In patients requiring intensive care, the cost is roughly \$2,000 per nosocomial UTI (Chen et al, 2009). The nosocomial costs for *E. coli* infections with relatively susceptible strains are considerably lower than for those caused by resistant gram-negative bacteria, which often require expensive parenteral antimicrobial therapy (Tambyah et al, 2002). Recently, the Center for Medicare and Medicaid Services (CMS) announced that it will no longer reimburse hospitals for the extra costs resulting from catheter-associated UTIs.

Pathogenesis

Bacteria enter the urinary tract of a catheterized patient by several routes. Bacteria can be introduced at the time of initial catheter placement by either mechanical inoculation of urethral bacteria or contamination from poor technique. Subsequently, the bacteria most commonly gain access via a periurethral or intraluminal route (Stamm, 1991). In women, periurethral entry is the most prevalent. Daifuku and Stamm (1984) found that among 18 women who developed catheter-associated bacteriuria, 12 had antecedent urethral colonization with the infecting strain. Bacteria may also enter the drainage bag and follow the intraluminal route to the bladder. This route is particularly common in patients who are clustered among other patients with indwelling catheters (Maizels and Schaeffer, 1980; Tambyah et al, 1999).

The urinary catheter system provides a unique environment that allows for two distinct populations of bacteria: those that grow within the urine and another population that grows on the catheter surface. A biofilm represents a microbial environment of bacteria embedded in an extracellular matrix of bacterial products and host proteins that often lead to catheter encrustation (Stamm, 1991; Bonadio et al, 2001). Certain bacteria, particularly of the *Pseudomonas* and *Proteus* species, are adept at biofilm growth, which

may explain their higher incidence in this clinical setting (Moblely and Warren, 1987). The uropathogens isolated from the catheterized urinary tract often differ from those found in noncatheterized ambulatory patients. *E. coli* is still the most common organism isolated, but *Pseudomonas*, *Proteus*, and *Enterococcus* species are very prevalent (Warren, 1991). In patients with long-term catheterization of more than 30 days, the bacteriuria is usually polymicrobial and the presence of four or five pathogens is not uncommon (Warren et al, 1982). Although certain species may persist for long periods, the bacterial populations in these patients tend to be dynamic.

Clinical Presentation

Most patients are asymptomatic. Suprapubic discomfort and development of fever, chills, or flank pain may indicate a symptomatic UTI.

Laboratory Diagnosis

Significant bacteriuria in patients with catheters is present when greater than 100 cfu/mL is present because even this low level progresses to greater than 10^5 cfu/mL in almost all patients (Maizels and Schaeffer, 1980; Stark and Maki, 1984). Pyuria is not a discriminate indicator of infection in this population.

Management

Careful aseptic insertion of the catheter and maintenance of a closed dependent drainage system are essential to minimize development of bacteriuria. The catheter-meatal junction should be cleaned daily with water, but antimicrobial agents should be avoided because they lead to colonization with resistant pathogens, such as *Pseudomonas*.

Incorporation of silver oxide (Schaeffer et al, 1988) or silver alloy (Saint et al, 1998) into the catheter and hydrogen peroxide into the drainage bag has been reported to decrease the incidence of bacteriuria in some studies (Schaeffer et al, 1988) but not in other populations (Stamm, 1991). The major benefit of silver alloy is in decreasing the likelihood of bacteriuria in hospitalized adults catheterized for the short-term (Saint et al, 2000; Newton et al, 2002; Brosnahan et al, 2004). If an asymptomatic catheterized patient has had an indwelling catheter for 3 or more days and will have the catheter removed, a dipstick test can be used to rule out bacteriuria (Tissot et al, 2001). Concurrent administration of systemic antimicrobial agents transiently decreases the incidence of bacteriuria associated with short-term catheterization, but after 3 to 4 days the incidence of bacteriuria is similar to the rate in catheterized patients not taking systemic antimicrobials agents, and the prevalence of resistant bacteria and side effects is substantial. The concept of instilling nonvirulent bacteria into the bladder to completely block colonization and infection by pathogens has been tested in patients with spinal cord injuries (Hull et al, 2000). Patients successfully colonized with the nonvirulent strain had reduced symptomatic UTI and a subjective improvement in quality of life.

Patients with indwelling catheters should be treated only if they become symptomatic (e.g., febrile). Urine cultures should be performed before initiating antimicrobial therapy. The antimicrobial agent should be discontinued within 48 hours of resolution of the infection. If the catheter has been indwelling for several weeks, encrustation may shelter bacteria from the antimicrobial agent; therefore the catheter should be changed.

When a catheter is to be removed and there is a high probability of bacteriuria or the dipstick test is positive, a culture should be obtained 24 hours before removal (Tissot et al, 2001). If the probability is low or the dipstick is negative, a culture may not be necessary. The patient should be started on empirical antimicrobial therapy such as TMP-SMX or a fluoroquinolone just before decatheterization and maintained on therapy for 2 days. A post-therapy culture should be obtained 7 to 10 days later to confirm the eradication of the bacteriuria.

KEY POINTS: CATHETER-ASSOCIATED BACTERIURIA

- Careful aseptic insertion of the catheter and maintenance of a closed, dependent drainage system are essential to minimize development of bacteriuria.
- The development of catheter-associated bacteriuria is inevitable.
- If an infection is suspected in a catheterized patient, a culture should be obtained and antimicrobial therapy initiated before decatheterization.
- Only symptomatic catheter-associated UTIs require treatment.
- Antimicrobial therapy should be continued for 2 to 3 days and a post-therapy culture obtained 7 to 10 days later.

MANAGEMENT OF URINARY TRACT INFECTIONS IN PATIENTS WITH SPINAL CORD INJURY

Patients with spinal cord injury have unique concerns that affect the risk, diagnosis, and management of UTIs, which are all considered complicated.

Epidemiology

UTIs are among the most common urologic complications of spinal cord injury. It has been estimated that approximately 33% of spinal cord-injured patients have bacteriuria at any time (Stover et al, 1989) and that eventually almost all spinal cord-injured patients will become bacteriuric and many will suffer significant morbidity and mortality. One prospective study of patients on intermittent catheterization or condom catheterization reported an incidence of significant bacteriuria of 18 episodes per person per year and an annual incidence of febrile UTIs of 1.8 per person per year (Waites et al, 1993a). In addition, UTI is the most common cause of fever in the spinal cord-injured patient (Beraldo et al, 1993). The 1992 National Institute on Disability and Rehabilitation Research Consensus Conference examined the problems associated with UTIs in spinal cord-injured patients (National Institute on Disability and Rehabilitation Research, 1993). Among the risk factors identified were impaired voiding, overdistention of the bladder, elevated intravesical pressure, increased risk of urinary obstruction, vesicoureteral reflux, instrumentation, and increased incidence of stones. Other factors that have been implicated are decreased fluid intake, poor hygiene, perineal colonization, decubiti, and other evidence of local tissue trauma, and reduced host defense associated with chronic illness (Gilmore et al, 1992; Waites et al, 1993a).

Pathogenesis

The method of bladder management has profound impact on UTI. The National Institute on Disability and Rehabilitation Research Consensus Conference noted that indwelling catheters were most likely to lead to UTI and that the vast majority of patients with an indwelling catheter for 30 days are bacteriuric (National Institute on Disability and Rehabilitation Research, 1993). Suprapubic catheters and indwelling urethral catheters eventually have an equivalent infection rate (Kunin et al, 1987; Tambyah and Maki, 2000; Biering-Sorensen, 2002). However, the onset of bacteriuria may be delayed using a suprapubic catheter compared with a urethral catheter. During a 2-year period, 170 patients with spinal cord injury were evaluated regarding type of urinary drainage and infection (Warren et al, 1982). In patients using indwelling urethral catheters, all urine cultures were positive. The corresponding values for the suprapubic catheter group were 44%. Condom drainage systems are also associated with an incidence of bacteriuria from 63% (Dukes, 1928) to almost 100% (Pyrah et al, 1955).

Since its introduction by [Lapides and colleagues \(1972\)](#), clean (but not sterile) intermittent catheterization (CIC) has earned general recognition in the management of spinal cord injury patients ([National Institute on Disability and Rehabilitation Research, 1993](#)). Although never rigorously compared with indwelling urethral catheterization, CIC has been shown to decrease lower tract complications by maintaining low intravesical pressure and reducing the incidence of stones ([Stover et al, 1989](#)). CIC also appears to reduce complications associated with an indwelling catheter, such as UTI, fever, bacteremia, and local infections such as epididymitis and prostatitis. [Weld and Dmochowski \(2000\)](#) followed 316 patients with spinal cord injury with different bladder management for a mean of 18.3 years and recorded all complications. The CIC group had statistically significantly lower complication rates compared with the urethral catheterization group and no significantly higher complication rates relative to all other management methods for each type of complication studied. Thus it is generally agreed that CIC places patients with spinal cord injury at the lowest risk for significant long-term urinary tract complications ([Stamm, 1975](#)).

There is conflicting evidence over the value of sterile versus nonsterile or “no touch” methods of CIC. Some studies have reported a lower incidence of infection in patients treated with sterile techniques ([Foley, 1929](#)), whereas others have not ([Pyrah et al, 1955](#); [Nyren et al, 1981](#)). [Bennett and coworkers \(1997\)](#) reported on a sterile method of CIC that uses an introducer tip to bypass the distal 1.5 cm of the urethra and showed a significant decrease in UTI with the use of the urethral introducer tip. Different types of catheters have been used for CIC. The low-friction catheters might be less traumatic for the urethra ([Casewell and Phillips, 1977](#); [Garibaldi et al, 1980](#)), but their impact on bacteriuria and UTI has to be studied.

Clinical Presentation

The majority of patients with spinal cord injury with bacteriuria are asymptomatic. Because of a loss of sensation, patients usually do not experience frequency, urgency, or dysuria. More often, they complain of flank, back, or abdominal discomfort, leakage between catheterizations, increased spasticity, malaise, lethargy, and/or cloudy, malodorous urine. UTI is the most common cause of fever in spinal cord-injured patients ([Beraldo et al, 1993](#)).

Bacteriology and Laboratory Diagnosis

Urinalysis will show bacteriuria and pyuria. Pyuria is not diagnostic of infections because it may occur from the irritative effects of the catheter. The National Institute on Disability and Rehabilitation Research Consensus Statement recommended the following criteria for the diagnosis of significant bacteriuria in spinal cord-injured patients ([National Institute on Disability and Rehabilitation Research, 1993](#)). Any detectable bacteria from indwelling or suprapubic catheter aspirates was considered significant because the vast majority of patients with an indwelling catheter and low-level bacteriuria showed an increase to greater than 10^5 cfu/mL within a short period of time ([Cardenas and Hooton, 1995](#)). For patients on CIC, greater than or equal to 10^2 cfu/mL was considered significant. For catheter-free males, a clean voided specimen showing greater than or equal to 10^4 cfu/mL was considered significant.

Bacteriuria in patients with spinal cord injury differs from that in patients with intact spinal cords in its etiology, complexity, and antimicrobial susceptibility and is influenced by the type and duration of catheterization. *E. coli* is isolated in approximately 20% of patients. Enterococci, *P. mirabilis*, and *Pseudomonas* are more common among spinal cord-injured patients than patients with intact spinal cords. Other common organisms are *Klebsiella* species, *Serratia* species, *Staphylococcus*, and *Candida* species. Most bacteriuria in short-term catheterization is of a single organism, whereas patients catheterized for longer than a month will usually demonstrate a polymicrobial flora caused by a wide

range of gram-negative and gram-positive bacterial species ([Edwards et al, 1983](#)). Such specimens commonly have two to four bacterial species, each at concentrations of 10^5 cfu/mL or more ([Monson and Kunin, 1974](#); [Nickel et al, 1987](#)). Some may have up to six to eight species at that concentration ([Monson and Kunin, 1974](#)). This phenomenon is due to an incidence of new episodes of bacteriuria approximately every 2 weeks and the ability of these strains to persist for weeks and months in the catheterized urinary tract ([Edwards et al, 1983](#); [Gabriel et al, 1996](#)). Two of the most persistent species are *E. coli* and *Providencia stuartii*. *P. stuartii* is rarely found outside the long-term catheterized urinary tract and may use the catheter itself as a niche ([Lindberg et al, 1975](#); [Hockstra, 1999](#)).

Management

Because of the diverse flora and high probability of bacterial resistance, a urine culture must be obtained before initiating empirical therapy. For afebrile patients, an oral fluoroquinolone is the agent of choice ([Cardenas and Hooton, 1995](#)). β -Lactams, TMP-SMX, and nitrofurantoin are not recommended because of the high prevalence of bacterial resistance to these drugs. An indwelling catheter should be changed to ensure maximal drainage and eliminate bacterial foci in catheter encrustations. Spinal cord-injured patients with fever or chills are usually admitted and treated with a parenteral aminoglycoside and a penicillin or a third-generation cephalosporin ([Cardenas and Hooton, 1995](#)). In this patient population consultation with a physician with expertise in antimicrobial management may be necessary, especially in a patient with recurrent infections.

If clinical improvement does not occur within 24 to 48 hours, reculture and adjustment of antimicrobial therapy based on the initial culture and susceptibility should be performed. Imaging studies should be obtained to rule out obstruction, stones, and abscess. The duration of therapy is not established, but 4 to 5 days is recommended for the mildly symptomatic patient and 10 to 14 days for sicker patients ([Cardenas and Hooton, 1995](#)). Post-therapy cultures are usually not necessary because asymptomatic recolonization is common and not clinically significant. However, if a urea-splitting bacterium is identified, a follow-up culture should be obtained to ensure its eradication. Spinal cord-injured patients with recurrent symptomatic UTIs should undergo urinary tract imaging and urodynamic testing and a review of their bladder management program with particular attention to catheter drainage, intermittent catheterization techniques, and frequency of intermittent catheterization or voiding schedule ([Cardenas and Hooton, 1995](#)).

Antimicrobial prophylaxis is not supported for most patients who have neurogenic bladder caused by spinal cord injury ([Morton et al, 2002](#)). Antimicrobial prophylaxis did not significantly decrease symptomatic UTIs and resulted in an approximately twofold increase in antimicrobial-resistant bacteria.

Recurrent UTIs may be associated with high storage pressures, and intervention to decrease storage pressure may decrease the incidence of symptomatic UTI. Evidence from studies in spinal cord-injured patients suggests that bladder catheterization for longer than 10 years is associated with an increased risk of carcinoma of the bladder. [West and colleagues \(1999\)](#) examined two databases with more than 33,000 spinal cord-injured patients and identified 130 patients with bladder cancer (0.4%) during a 5-year period. Several risk factors for bladder cancer have been proposed. Vereczky and associates (cited in [Weyrauch and Bassett, 1951](#)) tested different risk factors based on the outcome of 153 spinal cord-injured patients in which 7 were diagnosed with bladder cancer. Of a total of 31 possible predictors, only duration of catheterization was significant. Chronic infection and inflammation of the bladder mucosa could be the carcinogenic stimulus in these patients ([Pyrah et al, 1955](#)). Nitrosamines produced in infected urine have also been implicated ([Najenson et al, 1969](#)).

For further discussion of spinal cord injury and urinary infection, see Chapter 75.

KEY POINTS: MANAGEMENT OF URINARY TRACT INFECTION IN PATIENTS WITH SPINAL CORD INJURY

- UTI in patients with spinal cord injury commonly presents as fever; flank, back, or abdominal discomfort; leakage between catheterizations; increased spasticity; malaise; lethargy; and/or cloudy, malodorous urine.
- The majority of spinal cord-injured patients with bacteriuria are asymptomatic.
- Only symptomatic patients require therapy.
- Urine culture before the initiation of empirical therapy is essential because spinal cord-injured patients often culture diverse flora with a high probability of bacterial resistance.
- Clean intermittent catheterization places patients with spinal cord injury at the lowest risk for significant long-term urinary tract complications.
- Chronic infection can be carcinogenic.

OTHER INFECTIONS

Fournier Gangrene

Fournier gangrene is a potentially life-threatening form of necrotizing fasciitis involving the male genitalia. It is also known as idiopathic gangrene of the scrotum, streptococcal scrotal gangrene, perineal phlegmon, and spontaneous fulminant gangrene of the scrotum (Fournier, 1883, 1884). As originally reported by Baurienne in 1764, and by Fournier in 1883, it was characterized by an abrupt onset of a rapidly fulminating genital gangrene of idiopathic origin in previously healthy young patients that resulted in gangrenous destruction of the genitalia. The disease now differs from these descriptions in that it involves a broader age range, including older patients (Bejanga, 1979; Wolach et al, 1989), follows a more indolent course, and has a less abrupt onset; and, in approximately 95% of the cases, a source can now be identified (Macrea, 1945; Burpee and Edwards, 1972; Kearney and Carling, 1983; Jamieson et al, 1984; Spirnak et al, 1984).

Infection most commonly arises from the skin, urethra, or rectal regions. An association between urethral obstruction associated with strictures and extravasation and instrumentation has been well documented. Predisposing factors include diabetes mellitus, local trauma, paraphimosis, periurethral extravasation or urine, perirectal or perianal infections, and surgery such as circumcision or herniorrhaphy. In cases originating in the genitalia, specifically as a result of urethral obstruction, the infecting bacteria probably pass through Buck fascia of the penis and spread along the dartos fascia of the scrotum and penis, Colles fascia of the perineum, and Scarpa fascia of the anterior abdominal wall. In view of the typical foul odor associated with this condition, a major role for anaerobic bacteria is likely. Wound cultures generally yield multiple organisms, implicating anaerobic-aerobic synergy (Meleney, 1933; Miller, 1983; Cohen, 1986). Mixed cultures containing facultative organisms (*E. coli*, *Klebsiella*, enterococci) along with anaerobes (*Bacteroides*, *Fusobacterium*, *Clostridium*, microaerophilic streptococci) have been obtained from the lesions.

Clinical Presentation

Patients frequently have a history of recent perineal trauma, instrumentation, urethral stricture associated with sexually transmitted disease, or urethral cutaneous fistula. Pain, rectal bleeding, and a history of anal fissures suggest a rectal source of infection. Dermal sources are suggested by history of acute and chronic infections of the scrotum and spreading recurrent hidradenitis suppurativa or balanitis.

The infection commonly starts as cellulitis adjacent to the portal of entry. Early on, the involved area is swollen, erythematous, and tender as the infection begins to involve the deep

fascia. Pain is prominent, and fever and systemic toxicity are marked (Paty and Smith, 1992). The swelling and crepitus of the scrotum quickly increase, and dark purple areas develop and progress to extensive gangrene. If the abdominal wall becomes involved in an obese patient with diabetes, the process can spread very rapidly. Specific genitourinary symptoms associated with the condition include dysuria, urethral discharge, and obstructed voiding. Alterations in mental status, tachypnea, tachycardia, and temperature greater than 38.3°C (101°F) or less than 35.6°C (96°F) suggest gram-negative sepsis.

Laboratory Diagnosis and Radiologic Findings

Anemia occurs secondary to a decreased functioning erythrocyte mass caused by thrombosis and ecchymosis coupled with decreased production secondary to sepsis (Miller, 1983). Elevated serum creatinine levels, hyponatremia, and hypocalcemia are common. Hypocalcemia is believed to be secondary to bacterial lipases that destroy triglycerides and release free fatty acids that chelate calcium in its ionized form.

Because crepitus is often an early finding, a plain film of the abdomen may be helpful in identifying air. Scrotal ultrasonography is also useful in this regard. Biopsy of the base of an ulcer is characterized by superficially intact epidermis, dermal necrosis, and vascular thrombosis and polymorphonuclear leukocyte invasion with subcutaneous tissue necrosis. Stamenkovic and Lew (1984) noted that the use of frozen sections within 21 hours after the onset of symptoms could confirm a diagnosis earlier and lead to early institution of appropriate treatment.

Management

Prompt diagnosis is critical because of the rapidity with which the process can progress. The clinical differentiation of necrotizing fasciitis from cellulitis may be difficult because the initial signs including pain, edema, and erythema are not distinctive. However, the presence of marked systemic toxicity out of proportion to the local finding should alert the clinician. Intravenous hydration and antimicrobial therapy are indicated in preparation for surgical debridement. Antimicrobial regimens include broad-spectrum antibiotics (β -lactam plus β -lactamase inhibitor) such as piperacillin-tazobactam, especially if *Pseudomonas* is suspected, ampicillin plus sulbactam, or vancomycin or carbapenems plus clindamycin or metronidazole (Morpurgo and Galandiuk, 2002).

Immediate debridement is essential. In the patient in whom diagnosis is clearly suspected on clinical grounds (deep pain with patchy areas of surface hypoesthesia or crepitation, or bullae and skin necrosis), direct operative intervention is indicated. Extensive incision should be made through the skin and subcutaneous tissues, going beyond the areas of involvement until normal fascia is found. Necrotic fat and fascia should be excised, and the wound should be left open. A second procedure 24 to 48 hours later is indicated if there is any question about the adequacy of initial debridement. Orchiectomy is almost never required, because the testes have their own blood supply independent of the compromised fascial and cutaneous circulation to the scrotum. Suprapubic diversion should be performed in cases in which urethral trauma or extravasation is suspected. Colostomy should be performed if there is colonic or rectal perforation. Hyperbaric oxygen therapy has shown some promise in shortening hospital stays, increasing wound healing, and decreasing the gangrenous spread when used in conjunction with debridement and antimicrobials (Paty and Smith, 1992). Once wound healing is complete, reconstruction (e.g., using myocutaneous flaps) improves cosmetic results.

Outcome

The mortality rate averages approximately 20% (Cohen, 1986; Baskin et al, 1990; Clayton et al, 1990) but ranges from 7% to 75%.

Higher mortality rates are found in diabetics, alcoholics, and those with colorectal sources of infection who often have a less typical presentation, greater delay in diagnosis, and more widespread extension. Regardless of the presentation, Fournier gangrene is a true urologic emergency that demands early recognition, aggressive treatment with antimicrobial agents, and surgical debridement to reduce morbidity and mortality.

Periurethral Abscess

Periurethral abscess is a life-threatening infection of the male urethra and periurethral tissues. Initially, the area of involvement can be small and localized by Buck fascia. However, when Buck fascia is penetrated, there can be extensive necrosis of the subcutaneous tissue and fascia. Fasciitis can spread as far as the buttocks posteriorly and the clavicle superiorly. Rapid diagnosis and treatment are essential to reduce the morbidity and high mortality historically associated with this disease.

Pathogenesis

Periurethral abscess is frequently a sequela of gonorrhea, urethral stricture disease, or urethral catheterization. Frequent instrumentation is also associated with periurethral abscess formation. The source of the infecting organism is the urine. Gram-negative rods, enterococci, and anaerobes are most frequently identified. The presence of multiple organisms is common. Anaerobes, normal residents of the male urethra, are also frequently found in wound cultures.

Clinical Presentation

Presenting signs and symptoms include scrotal swelling in 94% of patients, fever (70%), acute urinary retention (19%), spontaneously drained abscess (11%), and dysuria or urethral discharge (5% to 8%). The average interval between initial symptoms and presentation is 21 days. Urinalysis of the first glass specimen reveals pyuria and bacteriuria.

Management

Treatment consists of immediate suprapubic urinary drainage and wide debridement. Antimicrobial therapy with an aminoglycoside and a cephalosporin is usually adequate for empirical coverage. More selective antimicrobial therapy can be instituted when the antimicrobial susceptibility of the organisms is available. Perineal urethrostomy or chronic suprapubic diversion occasionally has been helpful to prevent recurrences, and it should be considered in patients with diffuse stricture disease. The presence of a malignancy is unusual, but biopsy is important.

KEY POINTS: OTHER INFECTIONS

- Fournier gangrene is necrotizing fasciitis arising from the perineal skin, scrotum, urethra, or rectum.
- Emergent surgical debridement and broad-spectrum antimicrobial agents are the essentials of treatment of Fournier gangrene.
- Periurethral abscess can occur secondarily to urethral stricture or catheterization; treatment entails surgical debridement, suprapubic urinary drainage, and antimicrobial agents.

Inflammatory and Pain Conditions of the Male Genitourinary Tract: Prostatitis and Related Pain Conditions, Orchitis, and Epididymitis

J. Curtis Nickel, MD, FRCSC

Prostatitis and Chronic Pelvic Pain Syndrome

PROSTATITIS AND CHRONIC PELVIC PAIN SYNDROME

Historical Perspective

The clinical presentation, pathology, and microscopic evaluation of prostate-specific specimens of prostatitis patients were firmly established (Young et al, 1906) by the turn of the 20th century. Bacterial and cytologic localization studies of the lower urinary tract were described shortly thereafter (Hitchens and Brown, 1913) and standardized by 1930 (Von Lackum, 1927, 1928; Nickel, 1930, 1999c). The primary form of therapy for prostatitis during most of the 20th century was repetitive prostate massage (Farman, 1930; O'Connor, 1936; Henline, 1943; Campbell, 1957). Antimicrobial therapy became the mainstay of therapy with the introduction of sulfanilamide in the 1930s (Ritter and Lippow, 1938). However, even in the 1950s and 1960s, the significance of inflammatory cells and bacteria in the expressed prostatic secretion (EPS) was questioned (O'Shaughnessy et al, 1956; Bowers and Thomas, 1958; Bourne and Frishette, 1967), and it was even recognized that, in many cases, antibiotics were performing little better than placebo in the treatment of prostatitis (Gonder, 1963).

The next era of prostatitis management began in the 1960s with Meares and Stamey's (1968) description of the four-glass lower urinary tract segmented localization study. Prostatic massage as the mainstay of prostatitis therapy was abandoned, and antimicrobial therapy was rationalized for the very small percentage of patients with bacteria localized to prostate-specific specimens. Unfortunately, the vast majority of patients who were diagnosed with a nonbacterial cause continued to suffer the indignities of dismal urologic management (Nickel, 1998b). The establishment of new definitions and a classification system, better understanding of the etiopathogenesis, completion of randomized placebo-controlled trials with validated outcome indices, and the evolving insight that patients with prostatitis have variable clinical phenotypes have radically changed the way this condition is managed.

Epidemiology

Prostatitis is the most common urologic diagnosis in men younger than 50 years and the third most common urologic diagnosis in men older than 50 years after benign prostatic hyperplasia (BPH) and prostate cancer (Collins et al, 1998). As part of the International Consultation on Urologic Disease (ICUD) preparation for the male lower urinary tract symptoms (LUTS) guideline, the prevalence and incidence of prostatitis and/or chronic pelvic pain syndrome were estimated (Nickel et al, 2013b). Of 24 studies identified, 13 were from North America (Moon et al, 1997; Roberts et al, 1998; Collins et al, 1998, 2002; Nickel et al, 2001a;

Other Inflammatory and Pain Conditions of the Lower Urinary Tract

Roberts et al, 2002; Clemens et al, 2006, 2007; Daniels et al, 2007; Walz et al, 2007; Tripp et al, 2008; Wallner et al, 2009; Cheng et al, 2010); six from Asia (Ku et al, 2001; Tan et al, 2002; Cheah et al, 2003a; Kunishima et al, 2006; Liang et al, 2009; Lan et al, 2011); two from Europe (Mehik et al, 2000; Marszałek et al, 2007); two from Africa (Ejike et al, 2008; Tripp et al, 2012); and one from Australia (Ferris et al, 2010). Compiling the results of all studies, which included a total of 336,846 patients, a prevalence of 7.1% was estimated (range was from 2.2% to 16% with a median prevalence rate of 6.7%). Thirteen of these studies were population based and examined 48,824 patients. The prevalence overall was 7.7% with a range of 2.2% to 14.2% with a median prevalence rate of 8.4%. Five studies depended on physician diagnoses of prostatitis-like symptoms, including those using large databases to extract codes made by physicians for diagnosis. The reported prevalence ranged from 2.7% to 8.8%. The overall prevalence for these studies was 10,592 patients diagnosed out of 186,533 examined (mean 5.7%; median 8%). Five studies used patient recollection of a diagnosis of prostatitis. Of 101,489 patients, 9388 self-reported a diagnosis of prostatitis for a prevalence of 9.3%, ranging from 4.3% to 16%. The mean prevalence in studies according to continent of origin was 6.9% in North America, 7.5% in Asia, 7.6% in Australia, 8.6% in Europe, and 12.1% in Africa. A detailed discussion of this epidemiologic review can be found in the 2012 International Consultation report (Nickel et al, 2013b).

One study evaluated the incidence of male chronic pelvic pain syndrome (CPPS) in a managed care population (Clemens et al, 2005). The incidence was 3.30 cases per 1000 men per year, representing an incidence of 267,000 cases per year if these data can be extrapolated to the overall U.S. population. Prostatitis results in a substantial number of physician visits. The Urologic Diseases in America study reported an annualized visit rate of 1798 per 100,000 population for prostatitis (Pontari et al, 2007). Patients with symptoms of prostatitis appear to be at increased risk for persistent symptoms and for recurrent episodes. Participants with a previous diagnosis of prostatitis had a much higher cumulative probability of subsequent episodes of prostatitis (Roberts et al, 1998; Turner et al, 2004b).

In summary, the prevalence of prostatitis-like symptoms ranges from 2.2% to 16%, with a median prevalence rate approximating 7% for chronic prostatitis and CPPS.

Chronic prostatitis is associated with substantial costs and significant predicted resource consumption (Calhoun et al, 2004; Turner et al, 2004a; Duloy et al, 2007; Clemens et al, 2009). Overall spending in the United States for the diagnosis and management of prostatitis, exclusive of pharmaceutical spending, totaled 84 million dollars in 2000 and appears to be increasing (Pontari et al, 2007). This economic factor needs increased attention when evaluating the incidence and treatment of this prevalent condition.

KEY POINTS: EPIDEMIOLOGY

- Of men older than 18 years, 2% to 12% currently experience prostatitis-like symptoms.
- A median of 7% of men have chronic prostatitis or chronic pelvic pain syndrome.
- Prostatitis accounts for 6% to 8% of outpatient visits from men to urologists.

Histopathology

For the pathologist, prostatitis is defined as an increased number of inflammatory cells within the prostatic parenchyma (Cotran et al, 1999). Prostatic inflammation may or may not be noted in patients with a diagnosis of prostatitis (True et al, 1999), BPH (Nickel et al, 1999c), or prostate cancer (Zhang et al, 2000) and is noted in autopsy series in as many as 44% of prostate tissue samples from men without any definitive prostate disease (McNeal, 1968).

Consistently, fairly distinct although often coexisting patterns of chronic inflammation can be found in the prostate glands of patients with or without prostate disease. The most common pattern of inflammation is a lymphocytic infiltrate in the stroma immediately adjacent to the prostatic acini (Kohnen and Drach, 1979; Nickel et al, 1999c). The intensity of the inflammatory process varies considerably from only scattered lymphocytes to dense lymphoid nodules. Stromal lymphocytic infiltrates frequently coexist with periglandular inflammation. Sheets, clusters, and occasional nodules of lymphocytes and scattered plasma cells are seen within the fibromuscular stroma with no apparent relationship to the ducts and acini. Infiltrates of inflammatory cells restricted to the glandular epithelium and lumen are found in association with prostatitis and BPH but can be found in asymptomatic patients. The intraepithelial inflammatory cells may be neutrophils, lymphocytes, macrophages, or all of these, whereas neutrophils and macrophages are typically found in the lumen. A more detailed description of histologic inflammatory patterns in the prostate is available (Nickel et al, 2001d). Figure 13-1 illustrates the various inflammatory patterns seen in a prostate specimen from a patient with chronic prostatitis (CP).

Corpora amylacea, which may develop from the deposition of prostatic secretions around a sloughed epithelial cell or other irritant, are not usually associated with inflammation unless they become large enough to distend or obstruct the prostatic gland (Attah, 1975). Prostatic calculi may contribute to prostatic inflammation by obstructing central prostate ducts and thus preventing drainage or providing a nidus in which bacteria can survive host defenses and antibiotics (Meares, 1974; Roberts et al, 1997).

Granulomatous prostatitis presents a nonspecific and variable histologic pattern typified by heavy lobular, mixed, inflammatory infiltrates that include abundant histiocytes, lymphocytes, and plasma cells. Small, discrete granulomas may be present, or the pattern may be typified by well-defined granulomas. Granulomatous prostatic inflammation is a common consequence of surgery (Eyre et al, 1986) or bacille Calmette-Guérin (BCG) therapy (Lafontaine et al, 1997) and a rare event in patients with systemic tuberculosis (Saw et al, 1993).

Etiology**Microbiology**

Gram-Negative Uropathogens. Acute bacterial prostatitis is a generalized infection of the prostate gland and is associated with both lower urinary tract infection (UTI) and generalized sepsis. Chronic bacterial prostatitis is associated with recurrent lower UTIs (i.e., cystitis) secondary to areas of focal uropathogenic bacteria residing in the prostate gland. The most common cause

Figure 13-1. Histologic preparation of a prostate specimen demonstrating areas of glandular, periglandular, and stromal inflammation ($\times 400$). (Courtesy Dr. Alexander Boag.)

of bacterial prostatitis is the Enterobacteriaceae family of gram-negative bacteria, which originate in the gastrointestinal flora. The most common organisms are strains of *Escherichia coli*, which are identified in 65% to 80% of infections (Stamey, 1980; Lopez-Plaza and Bostwick, 1990; Weidner et al, 1991b; Schneider et al, 2003). *Pseudomonas aeruginosa*, *Serratia* species, *Klebsiella* species, and *Enterobacter aerogenes* are identified in a further 10% to 15% (Meares, 1987; Weidner et al, 1991b). However, in acute bacterial prostatitis, the organisms that result from previous manipulation of the lower urinary tract (including prostate biopsy) show different patterns of virulence and resistance (e.g., to quinolones and cephalosporins) compared with the organisms associated with spontaneous acute prostatitis (Millán-Rodríguez et al, 2006; Ha et al, 2008). Positive culture for extended-spectrum β -lactamase (ESBL) *E. coli* after prostate biopsy appears to be a risk factor for progression to CP (Oh et al, 2013).

Urovirulence factors play a significant role in the pathogenesis of bacterial prostatitis (Ruiz et al, 2002; Johnson et al, 2005). For instance, bacterial P fimbriae (or pili) bind to the urothelial receptors, and this subsequently facilitates ascent into the urinary tract as well as establishing deep infections in the prostate gland itself (Dilworth et al, 1990; Neal et al, 1990; Andreu et al, 1997). Colonization of the lower urinary tract by *E. coli* is also facilitated by the presence of type 1 fimbria, also known as *mannose-sensitive fimbria*. The receptor is a common moiety of the uroepithelial uromucoid; this association has been shown to be important in the development of cystitis in humans, and its presence in prostatitis has also been documented (Correll et al, 1996). Phase variation of type 1 pili during the establishment of acute bacterial prostatitis may occur in the setting of prostatitis (Schaeffer, 1991). Multiple virulence factors appear to be necessary to produce prostatitis (Mitsumori et al, 1999; Ruiz et al, 2002). Bacteria reside deep in the ducts of the prostate gland and when threatened with host defense and antimicrobial therapy tend to form aggregates (also called *biofilms*), which appears to be a protective mechanism allowing bacteria to persist in the prostate gland even when the cystitis is treated with antibiotics (Nickel and Costerton, 1993; Nickel et al, 1994). Hemolysin appears to be a virulence factor associated with *E. coli* acute prostatitis, but hemolysin may also be associated with increased ability of certain strains of *E. coli* to persist in the prostate as *biofilms* in patients with chronic bacterial prostatitis (Soto et al, 2007).

Gram-Positive Bacteria. Enterococci are believed to account for 5% to 10% of documented prostate infections (Drach, 1974a; Meares, 1987; Bergman, 1994). The role of other gram-positive organisms, which are also commensal organisms in the anterior urethra, is controversial (Fowler and Mariano, 1984a; Jimenez-Cruz

et al, 1984; Krieger et al, 2002). An etiologic role for gram-positive organisms such as *Staphylococcus saprophyticus*, hemolytic streptococci, *Staphylococcus aureus*, and other coagulase-negative staphylococci has been suggested by a number of authors (Drach, 1974a, 1986; Bergman, 1994). Nickel and Costerton (1992) have shown coagulase-negative *Staphylococcus* to be present in the EPS as well as transperineal prostate biopsy tissue of men with CP (microscopy and culture). Although this and other studies (Carson et al, 1982; Pfau, 1983; Bergman et al, 1989; Wedren, 1989) suggested that coagulase-negative staphylococci are involved in the pathogenesis of CP, these studies did not conclusively demonstrate that these bacteria were actually causing the inflammation and symptom complex rather than simply colonizing the prostate (Krieger et al, 2002). However, eradication of gram-positive bacteria in the prostate of men experiencing recent onset of prostatitis symptoms resulted in similar clinical results compared with men with gram-negative uropathogens localizing to the prostate (Magri et al, 2007a; Nickel and Xiang, 2008). In both cases, eradication of the bacteria localized to the prostate was strongly correlated with a good clinical outcome. However, the inconsistent localization of gram-positive bacteria in prostate-specific specimens from patients with CP suggests that this relationship may not be as strong as suggested (e.g., Krieger et al, 2005).

Anaerobic Bacteria. In studies in which the prostate-specific specimens were cultured anaerobically, anaerobic bacteria could be identified in a small number of patients (Nielsen and Justesen, 1974; Mardh and Colleen, 1975; Szoke et al, 1998). This has not been a consistent finding, and the role of anaerobic bacteria is essentially unknown.

Corynebacterium Infection. *Corynebacterium* species have usually been acknowledged as prostate nonpathogens but have been suggested as potential etiologic agents in this disease (Riegel et al, 1995; Domingue, 1998). Domingue and colleagues (1997) suggested that these difficult-to-culture coryneforms could be missed by routine culturing of EPS. Direct Gram staining of the EPS showed gram-variable pleomorphic coccobacillary rods that do not usually grow on routine media. The presence of these pleomorphic swollen rods was also shown by fluorescent acridine orange staining. Tanner and associates (1999), using polymerase chain reaction (PCR) techniques, were able to identify a bacterial signal (phylogenetically gram-positive organisms with predominance of *Corynebacterium* species) in 65% of 17 patients with CP. Approximately half these patients tended to respond to antimicrobial therapy, whereas patients in whom molecular signals for these bacteria could not be identified did not.

Chlamydial Infection. The evidence supporting the role of *Chlamydia trachomatis* as an etiologic agent in chronic prostatic inflammation is both confusing and conflicting. Mardh and Colleen (1972) found that one third of men with CP had antibodies to *C. trachomatis* compared with 3% of controls. Shortliffe and coworkers (1992) found that 20% of patients with nonbacterial prostatitis had antichlamydial antibody titers in the prostatic fluid. Koroku and associates (1995) detected *C. trachomatis*-specific immunoglobulin A (IgA) in 29% of men with chronic nonbacterial prostatitis. Bruce and colleagues (1981), on examination of early morning urine, prostatic fluid, or semen, found that 56% of patients with "subacute or chronic prostatitis" were infected with *C. trachomatis*. In a follow-up study, Bruce and Reid (1989) found that 6 of 55 men with abacterial prostatitis, including 31 believed to have chlamydial prostatitis, met strict criteria for positive diagnosis for chlamydial prostatitis based on identification of the organisms by culturing or immunofluorescence. Kuroda and colleagues (1989) identified *C. trachomatis* in the urethras of 20% of men with prostatitis. Other investigators have come to similar conclusions (Nilsson et al, 1981; Weidner et al, 1983). *Chlamydia* has also been isolated in prostate tissue specimens. Poletti and coworkers (1985) isolated *C. trachomatis* from prostate samples obtained by transrectal aspiration biopsy of men with "nonacute abacterial prostatitis." Abdelatif and colleagues (1991) identified intracellular *Chlamydia* through use of "in situ hybridization techniques" in transurethral prostate chips from 30% of men with histologic evidence of "chronic

abacterial prostatitis." Shurbaji and associates (1998) identified *C. trachomatis* in paraffin-embedded secretions in 31% of men with histologic evidence of prostatitis compared with none in patients with BPH without inflammation.

Although Mardh and Colleen (1972) suggested that *C. trachomatis* may be implicated in as many as one third of men with CP, their follow-up studies employing culturing and serologic tests could not confirm *C. trachomatis* as an etiologic agent in idiopathic prostatitis (Mardh and Colleen, 1975; Mardh et al, 1978). Shortliffe and Wehner (1986) came to a similar conclusion when their group evaluated antichlamydial antibody titers in prostatic fluid. Twelve percent of controls (compared with 20% of patients with nonbacterial prostatitis) had detectable antibodies. Berger and coworkers (1989) could not culture *C. trachomatis* from the urethras in men with CP, nor did they find a serologic or local immune response to *C. trachomatis* in such patients. Doble and associates (1989b) were not able to culture or detect by immunofluorescence *Chlamydia* in transperineal biopsy specimens of abnormal areas of the prostate in men with chronic abacterial prostatitis. Krieger and colleagues (1996b) were able to find *Chlamydia* in only 1% of prostate tissue biopsy specimens from men with CP. A further localization and culture series by Krieger and associates (2000) also failed to culture *Chlamydia* from either urethral or prostate specimens. Further elucidation of the role of chlamydial etiology of prostate infection is required before any definitive statement can be made regarding the association between isolation of this organism and its prostatic origin and effect (Weidner et al, 2002). That being said, antimicrobial therapy for presumed chlamydial prostate infection does result in amelioration of symptoms in many cases (Skerk et al, 2002b, 2003; Perletti et al, 2013).

Ureaplasma Infection. *Ureaplasma urealyticum* is a common organism isolated from the urethra of both asymptomatic men and men with nonspecific urethritis. Weidner and colleagues (1980) found high *U. urealyticum* concentrations in prostate-specific specimens in patients with signs and symptoms of abacterial prostatitis. Isaacs (1993) and associates cultured *U. urealyticum* from prostate secretions in 8% of patients with chronic nonbacterial prostatitis. Fish and Danziger (1993) found significant *U. urealyticum* concentrations in 13% of patients with prostatitis. Treatment with specific antimicrobial therapy cleared the organisms in all cases. Ohkawa and associates (1993a) isolated *U. urealyticum* cells from the prostates of 18 of 143 patients with CP. Antibiotics eradicated the organism in all, improved the symptoms in 10, and cleared the leukocytes in the EPS in 4 (Ohkawa et al, 1993b).

Other investigators (Mardh and Colleen, 1975), employing similar techniques, were unable to implicate *U. urealyticum* in patients with nonbacterial prostatitis. The problems encountered in all these studies include the absence of controls and the fact that it was difficult to account for possible urethral contamination in collecting specific prostate specimens. However, macrolides do appear to successfully improve CP symptoms when *Ureaplasma* or *Mycoplasma* organisms are identified in prostate specimens (Perletti et al, 2013).

Other Microorganisms. *Candida* (Golz and Mendling, 1991; Indudhara et al, 1992) and other mycotic infections such as aspergillosis and coccidioidomycosis (Schwarz, 1982; Chen and Schijj, 1985; Campbell et al, 1992; Truett and Crum, 2004) have been implicated in prostatic inflammation. However, in most cases it was usually an isolated finding in immunosuppressed patients or those with systemic fungal infection. Viruses (Doble et al, 1991; Benson and Smith, 1992) have also been implicated in prostatic inflammation, but no systematic evaluation of the role of these agents in prostatitis has been undertaken. *Trichomonas* has been described in the prostate glands of patients complaining of prostatitis-like symptoms (Kuberski, 1980; Gardner et al, 1996; Skerk et al, 2002a). *Helicobacter pylori* antibodies were positive in serum in 76% of men with CP compared with 62% in controls ($P < .05$). Although this is significantly greater, a large number of the patients without symptoms were seropositive (Karatas et al, 2010).

A newer concept is that it may not be the specific type of bacteria, but that the virulence of bacteria in men with CPPS may

be greater, resulting in symptoms or even causing symptoms that persist after eradication of the bacterial organism (Ivanov et al, 2009; Ivanov et al, 2010; Rudick et al, 2011; Galeone et al, 2013; Quick et al, 2013). It is interesting to note that the symptom patterns for patients who develop CPPS associated with previous bacterial infection may be different from those in patients who develop the syndrome not related to previous infection (Magri et al, 2013). **Nonculturable Microorganisms.** There are significant limitations to the culture techniques used to attempt to identify causative microorganisms associated with prostatitis (Lowentritt et al, 1995; Domingue et al, 1997; Domingue, 1998). Bacteria may exist in aggregated biofilms adherent to the prostatic ductal walls or within the obstructed ducts in the prostate (Nickel and MacLean, 1998). Nickel and Costerton (1993) observed that 60% of patients with previously diagnosed chronic bacterial prostatitis who progressed to sterile EPS cultures but continued to have symptoms despite antimicrobial therapy had positive cultures in prostate biopsy specimens showing an organism similar to the initial organism. As discussed earlier, such organisms appear to persist in small aggregates or biofilms in the ducts and acini of the prostate gland.

Berger and associates (1997) cultured urine specimens and transperineal prostate biopsies specifically for commensal and fastidious organisms. These investigators demonstrated that in prostate biopsy cultures men with evidence of inflammation in EPS are more likely to have bacteria isolated, positive cultures for anaerobic bacteria, higher total bacterial counts, and more bacterial species isolated than men without EPS inflammation. Krieger and colleagues (1996b), Riley and coworkers (1998) and Tanner and associates (1999), used a combination of clinical, culture, and molecular biologic methods (PCR) and found a strong correlation between inflammation and EPS and the detection of bacteria-specific 16S rRNA (gram-negative and gram-positive organisms) in the prostate tissue. But other researchers did not find any association between culture and PCR findings in men with nonbacterial prostatitis compared with men with prostatitis symptoms (Keay et al, 1999; Lee et al, 2003; Leskinen et al, 2003b). Nanobacteria are intriguing organisms that are difficult to isolate and culture, but may be implicated in some chronic urologic conditions including CP (Wood and Shoskes, 2006). A number of investigators (Shoskes et al, 2005; Zhou et al, 2008) have demonstrated the possibility that nanobacteria associated with and without prostatic calculi may be implicated in some cases of CP.

It has been estimated that less than 10% of all environmental bacteria have been identified (Domingue, 1998), so it is possible that fastidious and nonculturable microorganisms might be present in the prostate gland and that such organisms might be involved in the inflammatory process and subsequent development of symptoms.

Altered Prostate Host Defense

Risk factors that allow bacterial colonization or infection of the prostate with potentially pathogenic bacteria include intraprostatic ductal reflux (Kirby et al, 1982); phimosis (VanHowe, 1998); specific blood groups (Lomberg et al, 1986); unprotected penetrative anal rectal intercourse; UTI; acute epididymitis (Berger et al, 1987); indwelling urethral catheters and condom catheter drainage (Meares, 1998); and transurethral surgery, especially in men who have untreated, infected urine (Meares, 1989). Secretory dysfunction of the prostate characterized by an alteration in the composition of prostatic secretions can be diagnostic of patients with prostatitis—that is, a decrease in the levels of fructose; citric acid; acid phosphatase; the cations zinc, magnesium, and calcium; and the zinc-containing prostatic antibacterial factor—whereas pH, the ratio of isoenzymes lactate dehydrogenase-5 to lactate dehydrogenase-1, and inflammatory proteins such as ceruloplasmin and complement C3 are increased (Meares, 1989). These defined alterations in the prostate secretory function have also been blamed for adversely affecting the normal antibacterial nature of prostatic secretions. A decrease in prostatic antibacterial factor may reduce the intrinsic antibacterial activity of the prostatic fluid (Fair

et al, 1976), whereas the alkaline pH may hamper diffusion of certain basic antimicrobial drugs into the prostatic tissue and fluid (Fair and Cordonnier, 1978). However, caution is warranted because it is not known whether these compositional changes are a cause or a consequence of inflammation. It has further been suggested that the metabolic syndrome (Wang et al, 2013) and endothelial dysfunction with arterial stiffness (Shoskes et al, 2011) may be risk, mechanistic, or associated factors, likely through alteration of inflammatory pathways.

Dysfunctional Voiding

Anatomic or neurophysiologic obstruction resulting in high-pressure dysfunctional flow patterns has been implicated in the pathogenesis of prostatitis syndrome. Blacklock (1974, 1991) demonstrated that bladder neck, prostatic, and urethral anatomic abnormalities predisposed some men to developing prostatitis. Urodynamic studies confirm that many patients, particularly those with prostatodynia, have decreased maximal urinary flow rates and obstructive-appearing flow patterns (Barbalias et al, 1983; Ghobish, 2002). On video-urodynamic studies, many patients with prostatitis syndromes show incomplete funneling of the bladder neck as well as vesicourethral dyssynergic patterns (Kaplan et al, 1994, 1997; Hruz et al, 2003). Investigators (Dellabella et al, 2006) have described ultrasound alterations of the preprostatic sphincter in men with CP. In a study of 48 treatment-refractory CP patients with no associated infection, Hruz et al (2003) determined that 29 (60%) had bladder neck hypertrophy diagnosed by endoscopic and urodynamic criteria. This dyssynergic voiding may lead to an autonomic overstimulation of the perineal-pelvic neural system with subsequent development of a chronic neuropathic pain or neuromuscular state. Alternatively, this high-pressure, dysfunctional voiding may result in intraprostatic ductal reflux in susceptible individuals (see the next section).

Intraprostatic Ductal Reflux

Reflux of urine and possibly bacteria into the prostatic ducts has been postulated as one of the causative mechanisms involved in the pathogenesis of chronic bacterial and nonbacterial prostatic inflammation in some individuals. Anatomically, the ductal drainage of the peripheral zone is more susceptible than other prostatic zones to intraprostatic ductal reflux (Blacklock, 1974, 1991). Kirby and associates (1982) instilled a carbon particle solution into the bladders of men diagnosed with nonbacterial prostatitis. Carbon particles were found in the EPS macrophages and prostatic acini and ductal system after surgery in men with nonbacterial prostatitis. Persson and Ronquist (1996) noted high levels of urate and creatinine in EPS, which they postulated was caused by urine reflux into the prostatic ducts. Terai and colleagues (2000) provided molecular epidemiologic evidence for ascending infection in acute bacterial prostatitis.

Prostatic calculi are composed of substances found only in urine, not in prostatic secretions (Sutor and Wooley, 1974; Ramiraz et al, 1980), further evidence that urinary intraprostatic reflux occurs and likely contributes to the formation of prostatic calculi. If pathogenic bacteria reflux into the prostate gland, they may exist in protected aggregates within prostatic calculi themselves (Mazzoli, 2010). High culture counts of pathogens encrusted in prostatic calculi were demonstrated by Eykyn and colleagues (1974). This type of bacterial colonization in protective bacterial aggregates or biofilms associated with prostatic calculi may lead to recalcitrant CP and subsequent recurrent UTIs despite what seems to be adequate antibiotic therapy. Ludwig and coworkers (1994), employing transrectal ultrasonography, showed that men with chronic inflammatory prostatitis had a significantly increased frequency of prostatic calculi compared with men without prostate inflammation. It appears that prostatic calcification is common in patients with nonbacterial CP and is associated with greater inflammation, bacterial colonization, pelvic floor spasm, and symptom duration (Shoskes et al, 2007). The inflammation resulting from

chemical, bacterial, or immunologic stimulation has been shown to possibly cause an increase in intraprostatic pressures, measurable with transperineally inserted pressure transducers (Mehik et al, 2002).

Immunologic Alterations

The local prostatic immune system is activated by infection in bacterial prostatitis. In acute bacterial prostatitis, serum and prostatic fluid antigen-specific (i.e., bacterial antigen) IgG and IgA can be detected immediately after the onset of infection, and, after successful antibiotic therapy the levels decline to normal over the next 6 to 12 months (Meares, 1977; Fowler and Mariano, 1984b; Kumon, 1992; Meares, 1998). Prostate-specific antigen (PSA) levels can be markedly elevated during an acute episode of bacterial prostatitis (Dalton, 1989; Moon et al, 1992; Neal et al, 1992) and slowly resolve to normal levels over the course of 6 weeks to many months, provided there is no recrudescence of the infection. In chronic bacterial prostatitis, no serum Ig elevation is detected, whereas prostatic fluid IgA and IgG levels are both increased (Shortliffe and Wehner, 1986; Kumon, 1992). After successful antibiotic therapy, IgG levels return to normal after several months, but the IgA (particularly secretory IgA) levels remain elevated for almost 2 years (Shortliffe et al, 1981a, 1981b; Fowler and Mariano, 1984b). The presence of antibody-coated bacteria detected in urine, EPS, and semen is another prominent feature of chronic bacterial prostatitis (Riedasch et al, 1984, 1991).

Noninfectious inflammation (nonbacterial prostatitis or CPPS) might also be secondary to immunologically mediated inflammation caused by some unknown antigen or perhaps even related to an autoimmune process. IgA and IgM antibody levels (not microorganism specific) are elevated (Shortliffe and Wehner, 1986; Shortliffe et al, 1989, 1992), and similar antibodies as well as fibrinogen and complement C3 (Vinje et al, 1983; Doble et al, 1990) have been identified in prostatic biopsy samples from patients with CP. Both animal model studies (Donadio et al, 1998; Ceri et al, 1999; Lang et al, 2000; Breser et al, 2013; Chen et al, 2013; Quick et al, 2013) and human studies (Alexander et al, 1997; Batstone et al, 2002; Maake et al, 2003; Motrich et al, 2007) have suggested that prostatitis may be an autoimmune process. A number of candidates have been suggested for the self-antigen, including PSA (Ponniah et al, 2000). Other specific immunologic and neuroendocrine alterations such as cytokine production (Alexander et al, 1998; Jang et al, 2003), nerve growth factor (Miller et al, 2002), and mast cell activation (Done et al, 2012) have a subsequent role to play in the process of inflammation. Specifically, interleukin-10 (IL-10) has been implicated in the cause and clinical manifestations of CP (Miller et al, 2002; Shoskes et al, 2002), but other cytokines such as IL-1 β and tumor necrosis factor- α (TNF- α) have also been implicated (Nadler et al, 2000). IL-8 is the most common cytokine localized to the semen in men with CP (Khadra et al, 2006; Penna et al, 2007). There may be a genetic phenotype that promotes specific immunologic parameters that predispose to immunologically induced prostatic inflammation (Shoskes et al, 2002; Riley et al, 2002). These immunophenotypic patterns have even been observed in noninflammatory category IIIB CP/CPPS (Barghorn et al, 2001). One of the newest concepts emerging in the literature is that CPPS can exist through persistent immunologic mechanisms long after the bacteria have been eradicated (Ivanov et al, 2009, 2010; Rudick et al, 2011; Galeone et al, 2013; Quick et al, 2013). Whatever the initiating event, the immunologic cascade appears to have an important role in the development of prostatitis or CPPS in patients who develop prostatic inflammation (Moon, 1998; Kumon, 1999).

Chemically Induced Inflammation

Investigators have demonstrated that urine and its metabolites (e.g., urate) are present in the prostatic secretion of patients with CP (Persson and Ronquist, 1996). These investigators have hypothesized that the prostatic inflammation and subsequent symptoms

may be simply the result of a chemically induced inflammation secondary to the noxious substances in the urine that have refluxed into the prostatic duct.

Pelvic Floor Muscle Abnormalities

Investigators (Zermann et al, 1999) have proposed that the sensory or motor disturbances or both consistent with neural dysregulation of the lower urinary tract may be a consequence of acquired abnormalities in the central nervous system (CNS). Certainly, extraprostatic tenderness is identified in many patients with CP (Berger et al, 2007; Shoskes et al, 2008). Zermann and Schmidt (1999) described 103 patients with chronic pelvic pain whom they evaluated at a specialized neurourologic unit. They showed that a majority of the men had insufficient conscious control of their somatically innervated striated pelvic floor muscles. The patients showed various levels of identity with their pelvic floor muscles, but none were able to demonstrate the full range of pelvic floor contraction and relaxation repetitively and effortlessly. This was true whether or not there was evidence of inflammation. The researchers concluded that their findings reflect a functional disassociation between the CNS and the peripheral target, the pelvic floor muscles.

Other clinicians (Anderson, 1999; Potts, 2003; Hetrick et al, 2003; Shoskes et al, 2008; Anderson et al, 2009b) have proposed that the source of the pain is specifically at the pelvic musculature attachment area at the sacrum, coccyx, ischial tuberosity, pubic rami, and endopelvic fascia. These areas are immediately adjacent to the prostate and bladder and can be recognized by the demonstration of a hyperirritable spot or myofascial trigger point that is painful on compression. It is hypothesized that the formation of myofascial trigger points in this area results from mechanical abnormalities in the hip and lower extremities, chronic holding patterns such as those that occur during toilet training, sexual abuse, repetitive minor trauma and constipation, sports that create chronic pelvic stimulation, traumatic or unusual sexual activity, recurrent infections, and surgery (Anderson, 1999). More recently, it has been hypothesized that the pain experienced in some men with CPPS may be explained by pudendal nerve entrapment, which causes subsequent neuropathic pain (Antolak et al, 2002).

Neural Sensitization

The pain associated with the CP syndromes is similar in many respects to neuropathic pain. Objective autonomic nervous system changes can be observed in men with CP, suggesting that altered autonomic nervous system responses may be responsible for the pain associated with CPPS (Miller et al, 2002; Yang et al, 2003; Yilmaz et al, 2007, 2010). Pain that may have originated in the prostate or pelvic floor muscles, through mechanisms of cross-sensitization may have spread to adjacent organs and/or structures. Only recently have researchers begun to understand the complexity of overlapping neuropathways and possible mechanisms underlying pelvic organ crosstalk (Malykhina, 2007) including that from bowel (Takahashi et al, 2013). It now appears that actual measurable changes (functional and anatomic) in brain function can be observed in men with long-standing CPPS (Farmer et al, 2011; Moradasini et al, 2012).

It has recently been shown that men with CP showed evidence of dysfunctional hypothalamic-pituitary-adrenal axis function reflected in augmented awakening cortisol responses (Anderson et al, 2008), which can be further induced by stress (Anderson et al, 2009a). Another study evaluating adrenocortical hormone abnormalities in men with CP suggested that some men with this condition may even meet the diagnostic criteria for nonclassic congenital hyperplasia (Dimitrakov et al, 2008).

Psychosocial Associations

Psychological factors have always been considered to play an important role in the development or exacerbation of CP syndromes. Some researchers who have investigated the

psychopathology of these patients concluded that this syndrome should be viewed as a psychosomatic disorder (Mendlewich et al, 1971; Mellan et al, 1973; Keltikangas-Jarvinen et al, 1982). De la Rosette and associates (1993b) compared a group of 50 CP patients with a group of 50 patients seen for vasectomy and showed that although there were significant statistical differences between the groups (with CP patients demonstrating consistently higher personality disorder scores), these differences in scores were quite small compared with those between prostatitis and psychiatric patients. Berghuis and coworkers (1996) compared 51 prostatitis patients with a group of 34 men without any chronic pain condition and concluded that depression and psychological disturbances are common among prostatitis patients. Egan and Krieger (1994) compared prostatitis patients with those seeking treatment for chronic low back pain. Major depression was more common in prostatitis patients, but back pain caused more somatically focused depression and anxiety. Ku et al (2002) suggested that depression and weak masculine identity may be associated with an early stage of CP. A large case-control study confirmed that depression and panic disorders are significantly more common in men with chronic pelvic pain conditions than in controls (Clemens et al, 2008). These more recent studies demonstrate that psychological factors are involved in the disease, but it seems unjustified to label this group of patients as “neurotic” or as having a psychopathologic condition. However, recent analyses of the large prostatitis cohorts showed that psychological variables, such as depression, maladaptive coping techniques (e.g., pain catastrophizing, pain-contingent resting), poor social support, anxiety, and stress are important in CP outcomes (Tripp et al 2005; Ulrich et al, 2005; Tripp et al, 2006; Nickel et al, 2008c; Chung and Lin, 2013; Kwon and Chang, 2013). Factors such as catastrophizing are particularly important because they have been found to be stronger predictors of patient pain reports than depression (Tripp et al, 2006), indicating that negative cognitive appraisals of pain experience may be a primary target for psychosocial interventions. This may be especially important given the strong association that pain catastrophizing has been shown to have with elevations in depression, disability, and lower quality of life in patients with CP (Tripp et al, 2005, 2006; Nickel et al, 2008c; Hedelin, 2012; Tripp et al, 2013).

Association with Interstitial Cystitis or Bladder Pain Syndrome

Interstitial cystitis, now referred to by many as *bladder pain syndrome*, is an ill-defined CPPS occurring primarily in females, and a number of investigators have hypothesized that CPPS in men may have a similar cause (Pontari, 2006; Forrest et al, 2007). Unfortunately, the cause of interstitial cystitis remains unknown, but the

pathogenic mechanisms are theorized to be very similar to those that cause CP and/or chronic pelvic pain in men (Sant and Nickel, 1999; Eisenberg and Moldwin, 2003; Parsons 2003). Some researchers have proposed that in some patients diagnosed with prostatitis, a bladder-orientated interstitial cystitis mechanism actually accounts for the symptoms, and the prostate is only indirectly involved (Sant and Kominski, 1997). Certainly, the pain and voiding symptoms of interstitial cystitis and CP overlap to some extent (Miller et al, 1995; Novicki et al, 1998; Sant and Nickel, 1999; Forrest and Schmidt, 2004), and men with prostatitis diagnoses have cystoscopic (Berger et al, 1998), urodynamic (Siroky et al, 1981), and potassium sensitivity testing (Parsons and Albo, 2002; Parsons et al, 2005) findings very similar to those of patients with interstitial cystitis. However Yilmaz and coworkers (2004) did not confirm positive potassium sensitivity testing results in prostatitis patients, and Keay and colleagues (2004) showed that men diagnosed with CP (pain only) have normal antiproliferative factor (APF) activity whereas men diagnosed with interstitial cystitis (pain and irritative voiding symptoms) have detectable levels of urine APF.

Summary: Pathophysiology of Prostatitis and Related Syndromes

It is likely that nonbacterial prostatitis syndromes have a multifactorial cause—either a spectrum of causative mechanisms or, more likely, a progression or cascade of events that occur after one or more of the initiating factors described in the previous section. In a review on mechanisms involved in the pathogenesis of CP, Pontari and Ruggieri (2004) concluded that “the symptoms of chronic prostatitis/chronic pelvic pain syndrome appear to result from an interplay between psychological factors and dysfunction in the immune, neurological and endocrine systems.” Figure 13-2 describes a suggested pathophysiologic scenario that could potentially involve most of the proposed and interrelated causes described in this section.

KEY POINTS: ETIOLOGY

- Gram-negative Enterobacteriaceae and *Enterococcus* species are responsible for most cases of bacterial prostatitis.
- Other microorganisms might be implicated.
- Nonbacterial prostatitis and chronic pelvic pain syndromes are caused by an interrelated cascade of inflammatory, immunologic, endocrine, muscular, neuropathic, and psychologic mechanisms that begin with an initiator in a genetically or anatomically susceptible man.

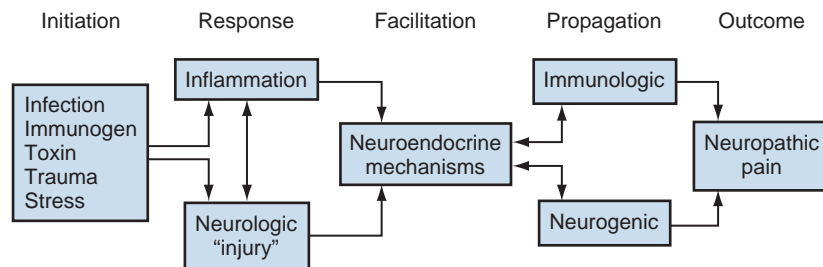

Figure 13-2. The cause and pathogenesis of chronic prostatitis/chronic pelvic pain syndrome (category III CPPS) appear to involve a pluricausal, multifactorial mechanism. An initiating stimulus, such as infection, reflux of some toxic or immunogenic urine substance, or perineal or pelvic trauma, starts a cascade of events in an anatomically or genetically susceptible man, resulting in a local response of inflammation or neurogenic injury or both. Further interrelated immunologic, neuropathic, endocrinologic, and psychologic mechanisms propagate or sustain the chronicity of the initial (or ongoing) event. The final outcome is the clinical manifestation of chronic perineal or pelvic pain and associated symptoms with local and central neuropathic mechanisms involving areas outside the prostate or pelvic area.

Definition and Classification

The traditional classification system is based on the landmark paper by Meares and Stamey (1968) describing the differential diagnosis of the prostatitis syndromes. This classic paper describes in great detail the serial cultures (and treatment) in four patients with CP and introduced the so-called *Meares-Stamey four-glass test*. This localization test, which segmentally assesses inflammation and cultures of the male lower urinary tract, is described in detail in the section on lower urinary tract evaluation. Based on 10 years of clinical experience with this test, a classification system describing four categories of prostatitis was described by Drach and colleagues in 1978. Differentiation of the four categories depended on an analysis of prostatic fluid, which included microscopy (examination for white blood cells (WBCs), inflammatory cell clumps, mucous debris, oval fat bodies, and macrophages) and culturing (identifying traditional uropathogens). This traditional classification system, which categorizes patients into those with acute bacterial prostatitis, chronic bacterial prostatitis, nonbacterial prostatitis, or prostatodynia, is described in Table 13-1.

The limitations of the traditional diagnostic algorithm and traditional classification system led to the development of the National

Institutes of Health (NIH) classification system (see Table 13-1) (Krieger et al, 1999). The new definition recognized that pain is the main symptom in “abacterial chronic prostatitis” (with variable voiding and sexual dysfunction), and it was the optimal criterion to differentiate CP patients from control patients or patients experiencing other genitourinary problems (e.g., BPH). The NIH classification differed from the traditional system in two main areas: the descriptions of category III CP/CPPS, and category IV asymptomatic inflammatory prostatitis.

Category I is identical to the acute bacterial prostatitis category of the traditional classification system. Category II is identical to the traditional chronic bacterial prostatitis classification, except that it now usually refers to patients with recurrent lower UTIs (with a prostate nidus of infection) (Schaeffer, 2006). Category III is defined as the “presence of genitourinary pain in the absence of uropathogenic bacteria detected by standard microbiological methodology.” This syndrome is further categorized into category IIIA, or inflammatory CP/CPPS (based on the presence of excessive leukocytes in EPSs or post-prostatic massage urine or semen), and category IIIB or noninflammatory CP/CPPS (no significant leukocytes in similar specimens). The inclusion of category IV, or asymptomatic inflammatory prostatitis, addressed one of the major problems and omissions of the traditional classification system. Patients are classified as having category IV prostatitis by the presence of significant leukocytes (or bacteria or both) in prostate-specific specimens (EPS, semen, and tissue biopsy specimens) in the absence of typical chronic pelvic pain.

The value of this classification system, not only in clinical research studies but also in clinical practice, has been generally accepted (Nickel et al, 1999d).

KEY POINT: CLASSIFICATION

- The National Institutes of Health classification of the prostatitis syndromes has now become recognized as the best system for research and clinical practice.

Clinical Presentation

Category I: Acute Bacterial Prostatitis

Acute bacterial prostatitis, category I, is a rare but important lower urinary tract infectious disease. It is characterized by an acute onset of pain combined with storage (irritative) and voiding (obstructive) urinary symptoms in a patient with manifestations of a systemic febrile illness. The patient typically reports urinary frequency, urgency, and dysuria. Obstructive voiding complaints including hesitancy, poor interrupted stream, strangury, and even acute urinary retention are common. The patient notes perineal and suprapubic pain and may have associated pain or discomfort of the external genitalia. In addition, there are usually significant systemic symptoms including fever, chills, malaise, nausea and vomiting, and even frank septicemia with hypotension. The combination and severity of symptoms in category I, acute bacterial prostatitis, vary from patient to patient. Approximately 5% of patients with acute bacterial prostatitis may progress to chronic bacterial prostatitis (Cho et al, 2005).

Category II: Chronic Bacterial Prostatitis

The most important clue in the diagnosis of category II, chronic bacterial prostatitis, is a history of documented recurrent UTIs. From 25% to 43% of patients diagnosed with chronic bacterial prostatitis through use of a four-glass test had a history of recurrent UTIs (Weidner and Ludwig, 1994; Wright et al, 1994). Patients may be relatively asymptomatic between acute episodes, or they may present with a long history of a CPPS, which is described extensively in the next section. The prevalence of bacterial prostatitis ranges

TABLE 13-1 Classification System for the Prostatitis Syndromes

TRADITIONAL	NATIONAL INSTITUTES OF HEALTH	DESCRIPTION
Acute bacterial prostatitis	Category I	Acute infection of the prostate gland
Chronic bacterial prostatitis	Category II	Chronic infection of the prostate gland
N/A	Category III Chronic pelvic pain syndrome (CPPS)	Chronic genitourinary pain in the absence of uropathogenic bacteria localized to the prostate gland employing standard methodology
Nonbacterial prostatitis	Category IIIA Inflammatory CPPS	Significant number of white blood cells in expressed prostatic secretions, post-prostatic massage urine sediment (VB3), or semen
Prostatodynia	Category IIIB Noninflammatory CPPS	Insignificant number of white blood cells in expressed prostatic secretions, post-prostatic massage urine sediment (VB3), or semen
N/A	Category IV Asymptomatic inflammatory prostatitis (AIP)	White blood cells (and/or bacteria) in expressed prostatic secretions, post-prostatic massage urine sediment (VB3), semen or histologic specimens of prostate gland

from 5% to 15% of prostatitis cases (Schaeffer et al, 1981; Krieger and Egan, 1991; Weidner and Ludwig, 1994). In one of the largest and most comprehensive clinical series, Weidner and associates (1991b) found significant bacteriuria (with uropathogenic organisms) in 4.4% of patients with symptoms of CP.

Category III: Chronic Prostatitis/Chronic Pelvic Pain Syndrome

The presenting symptoms of patients with inflammatory category IIIA CP/CPPS are indistinguishable from those of patients with noninflammatory category IIIB disease. The symptoms experienced by patients with CP/CPPS have been studied extensively by Krieger and colleagues (1996a). They evaluated 50 patients with CP/CPPS seen in a prostatitis clinic (compared with 75 control patients). Alexander and Trissel (1996) surveyed a cohort of 163 prostatitis patients on the Internet. These symptoms were best defined in the development of prostatitis symptom scores by Neal and Moon (1994), Krieger and colleagues (1996a), Nickel and Sorensen (1996), and Braehler and coworkers (1997). The predominant symptom in all these studies was pain, which was most commonly localized to the perineum, suprapubic area, and penis but can also occur in the testes, groin, or low back. Pain during or after ejaculation is one of the most prominent, important, and bothersome features in many patients (Shoskes et al, 2004). Storage and voiding urinary symptoms including urgency, frequency, hesitancy, and poor interrupted flow are associated with this syndrome in many patients. Erectile dysfunction and sexual disturbances have been reported in patients with CPPS (Mehik et al, 2001; Liang et al, 2004; Zaslaw et al, 2005; Muller and Mulhall, 2006; Smith et al, 2007a, 2007b; Lee et al, 2008b; Magri et al, 2008; Chung et al, 2012) but are not pathognomonic features of this syndrome. The best description of the CP/CPPS patient was provided by the NIH Chronic Prostatitis Cohort Study (Schaeffer et al, 2002). A detailed description of 488 men with CP/CPPS noted that the most frequently reported pain or discomfort was in the perineum, followed by pain or discomfort in the suprapubic area. Over half of the men had pain or discomfort during or after sexual climax (ejaculatory pain may be the most discriminatory symptom). A recent analysis of an international cohort of 1563 CP/CPPS patients was undertaken by Wagenlehner and colleagues (2013) to determine the prevalence and impact of pain locations and types to improve the strategy of individualized phenotypically guided treatment. This assessment confirmed that perineal pain or discomfort was the most prevalent pain symptom (63%), followed by testicular pain (58%), pain in the pubic area (42%), and pain in the penis (32%); reports of pain during ejaculation and voiding were 45% and 43%, respectively. Further study of this cohort showed that pain has more impact on quality of life than urinary symptoms; pain severity and frequency are more important than pain localization or type.

By definition, the syndrome becomes chronic after 3 months' duration. The symptoms tend to wax and wane over time; approximately one third of patients improve over 1 year (usually patients with a shorter duration of illness and fewer symptoms) (Nickel et al, 2002; Turner et al, 2004b; Probert et al, 2006b). An age-matched case-control study of risk factors in men with CP/CPPS (Pontari et al, 2005) showed that compared with asymptomatic controls, men with CP/CPPS reported a significantly greater lifetime prevalence of nonspecific urethritis (12% vs. 4%), cardiovascular disease (11% vs. 2%), neurologic disease (41% vs. 14%), psychiatric conditions (29% vs. 11%), and blood or infectious disease (41% vs. 20%).

The impact of this condition on health status is significant. The quality of life of many patients diagnosed with CP/CPPS is greatly diminished. Wenninger and associates (1996), employing a generic health status measure, the Sickness Impact Profile, showed that the mean scores were within the range of scores reported in the literature for patients with a history of myocardial infarction, angina, or Crohn disease. McNaughton Collins and coworkers

(2001b) employed similar quality-of-life assessment instruments in the NIH Chronic Prostatitis Cohort Study of almost 300 patients and confirmed this finding. These investigators noted that the mental health component was affected more than the physical component of the quality-of-life assessment. CP/CPPS patients' quality of life was lower than that observed in the most severely ill subgroups of men with congestive heart failure and diabetes mellitus. This significant impact on quality of life has also been reported in a cohort of CP/CPPS patients evaluated in a primary care setting (Turner et al, 2002). Patients with a diagnosis of CP/CPPS may have depression (Tripp et al, 2005, 2006), stress (Ulrich et al, 2005), or a history of abuse (sexual, physical, or emotional) (Hu et al, 2007). Depression, maladaptive coping techniques (e.g., catastrophizing and pain-contingent resting) and poor social support are associated with a poorer quality of life (Nickel et al, 2008c).

Category IV: Asymptomatic Inflammatory Prostatitis

Category IV, asymptomatic inflammatory prostatitis, by definition does not cause symptoms. The patients have BPH, an elevated PSA level, prostate cancer, or infertility. Subsequent microscopy of EPS or semen and/or histologic examination of BPH tissue, prostate cancer specimens, or prostate biopsy specimens disclose evidence of prostatic inflammation.

Evaluation

Symptom Assessment

For CP/CPPS, which is defined primarily by its symptom complex, analysis of specific prostatitis-like symptoms, the quality of life, the patient's functional status, and the patient's satisfaction with medical care will result in not only better evaluation of the prostatitis patient but also improved therapeutic follow-up. Scientifically validated symptom indices not only improve the care of patients but also optimize clinical decision making in terms of comparing clinical trial outcomes. Since the early 1990s, several different symptom indices have been described in clinical research (Neal and Moon, 1994; Krieger et al, 1996a; Nickel and Sorensen, 1996; Braehler et al, 1997; Chiang et al, 1997) and have been sporadically employed in clinical practice (McNaughton Collins and O'Leary, 1999). Although each of these symptom indices was successful at the time it was developed for the specific purpose or study, none was believed to be ideal for use in general research or clinical practice because they were not validated according to the rigorous standards that now must be met for an accepted urologic disease-specific index (O'Leary et al, 1992).

The NIH Chronic Prostatitis Collaborative Research Network (CPCRN) developed a reproducible and valid instrument to measure the symptoms and quality of life of patients with CP for use in research protocols as well as clinical practice (Litwin et al, 1999). The steps followed in the development of the NIH-Chronic Prostatitis Symptom Index (NIH-CPSI) included a systematic literature review, focus groups, cognitive testing, an expert panel review, a validation test, and psychometric analyses. The final CPSI consists of nine questions that address the three most important domains of the CP experience. Pain (which is the primary symptom of CP/CPPS) was captured in four questions that focused on its location, severity, and frequency. Urinary function, the second most important component of patients' symptoms, was captured in two questions, one concerning storage (irritative) and the other voiding (obstructive) function. The quality of life or impact was captured in three additional questions that asked about the effect of symptoms on daily activities. The NIH-CPSI (Fig. 13-3) has now been accepted by the international prostatitis research community as an accepted outcome measure (Nickel et al, 1999d) and has shown validity and responsiveness in primary care samples (Turner et al, 2003) and clinical trials (Probert et al, 2006a). It has been translated and validated in many languages other than English (Collins et al, 2001; Kunishima et al, 2002; Leskinen et al, 2003a; Schneider et al, 2004; Karakiewicz

NO PAIN AS BAD AS YOU CAN IMAGINE																																															

Figure 13-3. The National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI) captures the three most important domains of the prostatitis experience: pain (location, frequency, and severity), voiding (irritative and obstructive symptoms), and quality of life (including impact). This index is useful in research studies and clinical practice. (From Litwin MS, McNaughton Collins M, Fowler FJ, et al. The NIH Chronic Prostatitis Symptom Index [NIH-CPSI]: development and validation of a new outcome measure. *J Urol* 1999;162:369–75.)

et al, 2005). The symptom index has also proved its usefulness in the evaluation and follow-up of patients in general clinical urologic practice (Nickel, 1999d; Nickel et al, 2001c). Cut-off levels for pain severity categories were mild, 0 to 3; moderate, 4 to 6; and severe, 7 to 10 for CPSI item 4 (0 to 10); CPSI pain domain (0 to 21) scores were mild, 0 to 7; moderate, 8 to 13; and severe, 14 to 21 (Wagenlehner et al, 2013).

KEY POINT: SYMPTOM ASSESSMENT

- The validated National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI) is a useful research and clinical tool for evaluating chronic prostatitis and chronic pelvic pain syndrome patients.

Physical Examination

Physical examination is an important part of the evaluation of a patient with prostatitis, and although not confirmatory in making a definitive diagnosis, it is very helpful in further classifying the disorder and even directing therapy. It assists in ruling out other perineal, anal, neurologic, pelvic, or prostate abnormalities and is an integral part of the lower urinary tract evaluation by providing prostate-specific specimens (Nickel, 2002a).

In **category I**, acute bacterial prostatitis, the patient may be systemically toxic—that is, flushed, febrile, tachycardic, tachypneic, and even hypotensive. The patient usually has suprapubic discomfort and perhaps has clinically detectable acute urinary retention. Perineal pain and anal sphincter spasm may complicate the digital rectal examination. The prostate itself is usually described as hot, boggy, and exquisitely tender. The expression of prostatic fluid is believed to be totally unnecessary and perhaps even harmful.

The physical examination of a patient with **category II**, chronic bacterial prostatitis, and **category III** CPPS is usually unremarkable (except for pain). Careful examination and palpation of external genitalia, groin, perineum, coccyx, external anal sphincter (tone), and internal pelvic floor and side walls may pinpoint prominent areas of pain or discomfort (Shoskes et al, 2008; Anderson et al, 2009b). The findings of pelvic floor dysfunction and spastic pain, myofascial pain, or painful trigger points has significant implications for developing treatment plans. The digital rectal examination should be performed after the patient has produced preprostatic massage urine specimens (see later) and after the perineal and pelvic examination. The prostate may be normal in size and consistency, and it has also been described as enlarged and boggy (loosely defined by me as softer than normal). The degree of elicited pain during prostatic palpation is variable and is unhelpful in differentiating a prostatitis syndrome. The prostate should be carefully checked for prostatic nodules before a vigorous prostatic massage is performed to produce prostate-specific specimens (EPS and post-prostatic massage urine sample).

Lower Urinary Tract Cytologic Examination and Culture Techniques. In patients with category I, acute bacterial prostatitis, a urine culture is the only laboratory evaluation of the lower urinary tract required. It has been suggested that the vigorous prostatic massage necessary to produce EPS can exacerbate the clinical situation, although such fears have never been substantiated in the literature. A midstream urine specimen will show significant leukocytosis and bacteriuria microscopically, and culturing usually discloses typical uropathogens. Blood cultures may show the same organism.

In 1968, Meares and Stamey described the classic four-glass urine collection technique to distinguish urethral, bladder, and prostate infections in men with CP, and for three decades this has remained the gold standard for the evaluation of this lower urinary tract syndrome. The voided bladder-1 (VB1) specimen includes the first 10 mL of urine and represents the urethral specimen. The voided bladder-2 (VB2) specimen is similar to a midstream urine collection and represents the bladder urine. EPS should be collected directly into a sterile container during prostatic massage. The voided bladder-3 (VB3) specimen, the first 10 mL of urine voided after prostatic massage, includes any EPS trapped in the prostatic urethra. All four specimens are to be sent to the clinical microbiology laboratory for quantitative culture. Aliquots of the three urine specimens are centrifuged for 5 minutes and the sediment examined under high power for leukocytes (including aggregates of leukocytes), macrophages, oval fat bodies, erythrocytes, bacteria, and fungal hyphae. A wet mount of a drop of EPS can be examined under a coverslip in a similar manner. Some researchers (Muller et al, 2001; Krieger et al, 2003) point out that quantitative determination of the EPS WBC concentration by a counting chamber method is superior to the standard wet mount method but probably only indicated in research studies. In fact, the NIH Chronic Prostatitis Cohort Study (Schaeffer et al, 2002; Nickel et al, 2003a) suggested that leukocyte determination did not appear to add significant clinical information to the assessment of a patient with CP/CPPS.

4-Glass Test (Meares-Stamey Test)

Classification	Specimen	VB1	VB2	EPS	VB3
CAT II	WBC	–	+/-*	+	+
	Culture	–	+/-*	+	+
CAT IIIA	WBC	–	–	+	+
	Culture	–	–	–	–
CAT IIIB	WBC	–	–	–	–
	Culture	–	–	–	–

Figure 13-4. Technique and interpretation of the Meares-Stamey four-glass lower urinary tract localization test for chronic prostatitis and chronic pelvic pain syndrome. CAT, category; EPS, expressed prostatic secretion; VB, voided bladder; WBC, white blood cell.

Figure 13-4 illustrates the technique and interpretation of the four-glass test.

Category II, chronic bacterial prostatitis, is diagnosed if there is a 10-fold increase in bacteria in the EPS or VB3 specimen compared with the VB1 and VB2 specimens. In a patient who has acute cystitis this localization is impossible, and in this case the patient can be treated with a short course (1 to 3 days) of therapy with an antibiotic such as nitrofurantoin, which penetrates the prostate poorly but eradicates the bladder bacteriuria. Subsequent localization of bacteria in the post-prostatic massage urine or EPS is then diagnostic of category II prostatitis. Category IIIA CP/CPPS is diagnosed when no uropathogenic bacteria are cultured, but excessive leukocytosis (usually defined as more than 5 to 10 WBCs per high-power field [HPF]) is noted in the prostate-specific specimens (EPS or VB3 or both). Category IIIB CP/CPPS is diagnosed when no uropathogenic bacteria are cultured and there is no significant leukocytosis noted on microscopic examination of EPS or the sediment of VB3.

Although the four-glass test remains the gold standard diagnostic evaluation of prostatitis patients, numerous surveys (Moon, 1997; Nickel et al, 1998a; McNaughton Collins and O'Leary, 1999; McNaughton Collins et al, 2000a) have confirmed that clinicians have more or less abandoned this time-consuming and expensive rigorous evaluation. The pre-massage and post-massage test (or two-glass test), originally suggested by Weidner and Ebner (1985) and popularized by Nickel (1995, 1996, 1997a), is a simple, cost-effective screen to categorize patients with CP. The patient provides a midstream pre-massage urine specimen and a urine specimen (initial 10 mL) after prostatic massage. Microscopy (sediment) and culturing of these two screening urine specimens allows categorization of the majority of patients with a CP syndrome. Figure 13-5 illustrates the technique and interpretation of the two-glass pre-massage and post-massage test.

In a retrospective personal series and a review of series in the literature, Nickel (1997a) noted that this test had 91% sensitivity and specificity compared with the gold standard Meares-Stamey test. Its limitations were thought to be the result of the exclusion of the urethral and EPS specimen. However, in patients without clinical urethritis, Krieger and associates (2000) demonstrated that urethral swabs are more efficient in picking up urethral inflammation than the VB1 specimen. But in this series of 235 patients, only 3% had more than 1 WBC/HPF. Therefore the urethral specimens rarely resulted in detection of significant urethral inflammation, and in this series rarely did cultured organisms change the direction of clinical therapy in patients with prostatitis (without clinical urethritis). In the same study (Krieger et al, 2000) comparing EPS with post-prostatic massage urine, the investigators demonstrated that EPS examination detected 76%, whereas post-massage urine

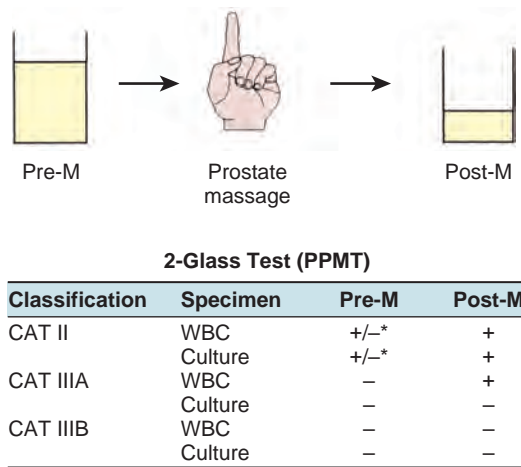

Figure 13-5. Technique and interpretation of the pre- and post-massage two-glass lower urinary tract localization test for chronic prostatitis and chronic pelvic pain syndrome. CAT, category; PPMT, pre- and post-massage test; WBC, white blood cell.

examination detected 82% of the patients who had inflammation on one or both tests. Ludwig and associates (2000), in a series of 328 patients in whom both EPS and a VB3 specimen were obtained, demonstrated that VB3 is almost as accurate as EPS (92% sensitivity; 99% specificity) in detecting prostate-specific inflammation. Seiler and associates (2003) came to the same conclusion in their study of 143 CP patients. Nickel and colleagues from the NIH CPCRN examined a cohort of 353 CP/CPPS men with complete four-glass data and noted that the two-glass test predicted a positive four-glass result with clinically acceptable accuracy (over 95% of men would have had the same diagnosis if the four-glass test were performed) (Nickel et al, 2006). This test, however, is only a screening test, and in patients in whom it is important to localize bacteria to the prostate versus the urethra (e.g., patients with recurrent UTIs, suspicion of urethral abnormality), a follow-up VB1 specimen or urethral swab may be very helpful. If typical urethral organisms are localized to the prostate when the pre-massage and post-massage test is used and the clinician is inclined to consider them pathogenic and subsequently treat the patients, urethral and EPS specimens to definitively localize the specific bacteria to the prostate are appropriate. As a general rule, it is always best to examine the EPS (if obtainable) microscopically.

The significance and diagnostic value of semen analysis in chronic bacterial prostatitis have been extensively debated and remain controversial. In a small study of 70 men with CP and 17 asymptomatic controls, Zagarra Montes and colleagues (2008) concluded that although a positive semen culture in a symptomatic patient may be useful to make a decision to start antibiotic treatment, a negative culture does not rule out the condition. Segmented lower urinary tract urine specimens are required for a definitive diagnosis. Data analyzed by Magri and associates (2009), in which 696 symptomatic patients were subjected to a four-glass test followed by semen culture and analysis, support the usefulness of semen analysis in the diagnostic workup of prostatitis patients but only when this test is used to complement the four-glass Meares and Stamey test.

Microbiologic Considerations

The Prostatitis Syndrome classification system depends on culturing for standard uropathogens. The Enterobacteriaceae (e.g., *E. coli*, *Serratia*, *Klebsiella*, *Proteus*, *Pseudomonas*) represent the most common uropathogens, followed by gram-positive enterococci. However, as discussed earlier in the section on etiology, other gram-positive organisms that typically colonize the urethra (*Staphylococcus epidermidis*, *S. saprophyticus*, *Streptococcus* species, *Corynebacterium*, and *Bacteroides*) can be localized to prostate specimens, including semen (>10-fold colony-forming unit count in prostate-specific specimens compared with pre-prostatic massage specimens), and their association with the prostatic inflammation symptom complex remains unclear. At this time, these patients are still considered to have category III CP/CPPS, but this may change as more research results become available and the current understanding of bacterial pathogenicity in the prostate gland evolves (Nickel and Moon, 2005; Nickel and Xiang, 2008). In patients with acute prostatitis, a blood culture should be considered, particularly if the patient has signs and symptoms of systemic infection (Etienne et al, 2010).

Cytologic Considerations

The differentiation of the two subtypes of category III CP/CPPS depends on cytologic examination of the urine or EPS or both. The urine specimens are centrifuged for 5 minutes; the sediment is resuspended under a coverslip and examined at high power (×300 to ×400), and the wet mount of a drop of EPS is examined under a coverslip at the same power. WBCs have traditionally been reported as numbers of leukocytes per high-power field (Fig. 13-6). There is no validated cutoff point for the level of WBCs per high-power field that is required to differentiate an inflammatory from a noninflammatory CP/CPPS. Although the suggested limits have ranged from as low as 2 (Anderson and Weller, 1979) to as high as 20 (Blacklock and Beavis, 1978), the consensus appears to favor 5 to 10 WBCs/HPF in EPS as the upper level of normal (Meares and Stamey, 1968; Pfau et al, 1978; Schaeffer et al, 1981). But inflammatory cells in the EPS fluctuate over time (Anderson and Weller, 1979; Schaeffer et al, 1981) and with the frequency of ejaculation (Jameson, 1967; Yavascaoglu et al, 1999). A disadvantage of looking at a drop of prostatic fluid or urine sediment is that the cells may clump or aggregate, which renders quantifying them virtually impossible. Also, an unstained specimen does not allow differentiation of the types of WBCs present (e.g., polymorphonuclear leukocytes, lymphocytes, monocytes, macrophages). If accuracy is required (e.g., for research), then the WBCs can be counted in a glass hemacytometer (so they may be quantified as cells per square millimeter) and subsequently stained to differentiate the inflammatory cell subtype (Anderson and Weller, 1979).

The clinical relevance of adding cytologic examination of semen specimens (which is difficult without special staining techniques) is unknown. Certainly, semen examination increases the percentage of patients identified as having inflammatory category IIIA CP/CPPS (Krieger et al, 2000).

Nickel and colleagues (2003a) compared the number of WBCs in the EPS in patients with CP/CPPS with the number in EPS specimens from normal asymptomatic control men and noted that although there was a statistically significant difference in WBC counts in the CP/CPPS men, the clinical significance was not apparent (i.e., 50% of CPPS men had >5 WBCs/HPF compared with 40% of control men). The relevance of examining urine and EPS for white cells in routine clinical practice has been challenged (Nickel et al, 2003a). In fact, my colleagues and I have not been able to confirm the association between histologically proven prostate inflammation and prostatitis symptoms (Nickel et al, 2007), further confusing the issue of whether it is necessary to determine prostate-specific specimen inflammation, which is really just a surrogate for prostate inflammation. However, some investigators (Nickel, 2002b) have recommended that a separate aliquot of urine be examined cytologically for malignant cells, particularly

KEY POINT: LOWER URINARY TRACT CULTURE TECHNIQUE

- The two-glass pre- and post-massage test is a simple, useful screen for inflammation and infection of the lower urinary tract in patients with chronic prostatitis.

Figure 13-6. A and B, Unstained photomicrographs showing individual white blood cells, clumps of white blood cells, and lipid-laden macrophages in the expressed prostatic secretion of a patient with category IIIA chronic pelvic pain syndrome (A, $\times 250$; B, $\times 400$).

if the symptom complex includes storage urinary symptoms, dysuria, and/or suprapubic or bladder pain.

Urodynamics

Pain is the dominant symptom in patients with CP/CPPS, but a wide constellation of storage and voiding symptoms is associated with this syndrome. Proposed causes to account for the persistent urinary symptoms include detrusor vesical neck or external sphincter dyssynergia, proximal or distal urethral obstruction, and fibrosis or hypertrophy of the vesical neck (Blacklock, 1974; Bates et al, 1975; Orland et al, 1985; Blacklock, 1986; Theodorou et al, 1999). These abnormalities can often be clarified and diagnosed by urodynamics, particularly video-urodynamics. Others have suggested that men with defined primary voiding dysfunction have been misdiagnosed with CP (Webster et al, 1980; Siroky et al, 1981; Murnaghan and Millard, 1984). Siroky and associates (1981) noted that urodynamics revealed that 50% of 47 men with recurrent urinary symptoms, perigenital pain, or both who had previously been diagnosed as having CP had bladder acontractility during a study with nonrelaxing perineal floor (striated muscle spasm) and that another 36% had detrusor overactivity with appropriate striated sphincter relaxation. Barbalias (1990) and Barbalias and colleagues (1983) noted decreased peak and mean urinary flow rates, a significantly elevated maximal urethral closing pressure, and incomplete funneling of the bladder neck accompanied by urethral narrowing at the level of the external urinary sphincter during voiding with urodynamic evaluation of men diagnosed with CP. Hellstrom and colleagues (1987) also noted elevated urethral pressures, “hyperreflexia” of the external urethral sphincter, and intraprostatic reflux in three patients with unremitting symptoms of chronic nonbacterial prostatitis.

Kaplan and associates (1994, 1996, 1997) postulated that chronic lower urinary tract symptoms in young men are often misdiagnosed as chronic nonbacterial prostatitis when in fact they indicate a cohort of men with undiagnosed chronic voiding dysfunction. This conclusion is based on the video-urodynamic studies of 137 consecutive men 50 years of age or younger diagnosed with CP that did not respond to standard therapy (Kaplan et al, 1996). These researchers demonstrated a variety of urodynamic abnormalities in this selected population, including 54% of patients with primary vesical neck obstruction, 24% with functional obstruction localized to the membranous urethra (pseudodyssynergia), 17% with impaired bladder contractility, and 5% with an acontractile bladder. They noted detrusor overactivity in 49% of the men. Simple documentation of uroflowmetry and residual urine bladder scan abnormalities may suggest proceeding to more sophisticated urodynamics (Ghobish, 2000). Other groups dispute the benefits

of urodynamics and have noted very few urodynamic abnormalities in the typical patients with classic CP symptoms (Mayo et al, 1998).

Endoscopy

Clinical experience (rather than controlled clinical studies) suggests that lower urinary tract endoscopy (i.e., cystoscopy) is not indicated in the majority of men with CP/CPPS. However, cystoscopy is indicated in patients in whom the history (e.g., hematuria), lower urinary tract evaluation (e.g., VB1 urinalysis), or ancillary studies (e.g., urodynamics) indicate the possibility of a diagnosis other than CP/CPPS. In these patients, lower urinary tract malignancy, stones, urethral strictures, bladder neck abnormalities, and other lower urinary tract abnormalities that can be surgically corrected occasionally are discovered. Cystoscopy can probably be justified in men whose condition is refractory to standard therapy.

Ultrasonography

Transrectal ultrasonography has become one of the best radiologic methods to evaluate prostate disease and has become an especially helpful clinical tool for the assessment of prostate volume and ultrasound guidance of biopsy needles. The diagnostic value of ultrasonography in differentiating benign from malignant prostate disease is controversial, and the further differentiation of the various benign conditions of the prostate is even more so. Di Trapani and colleagues (1988) described inhomogeneous echo structures, constant dilatation of periprostatic venous plexus, elongated seminal vesicles, and thickening of the inner septa in patients with prostatitis. Doble and Carter (1989) described seven ultrasound signs associated with the presence of symptoms of CP compared with controls, and although the sensitivity increased with higher leukocyte counts, the signs were not sufficiently specific to differentiate clinical groups.

Peeling and Griffiths (1984) described the heterogeneity of the echo pattern and prostatic calculi as ultrasound features related to prostatitis. Ludwig and coworkers (1994) described the ultrasound features such as prostatic calcifications and seminal vesicle abnormalities that appear to be indicative of signs of inflammation but not proof of the presence of CP. Harada and associates (1980) concluded that the presence of stones is not related to a specific prostate disease process. De la Rosette and colleagues (1992b) performed ultrasonography in 22 patients with nonbacterial prostatitis and compared the results with those of a control group of 22 patients without lower urinary tract symptoms. This study indicated that there were no significant differences in ultrasound patterns of patients with nonbacterial prostatitis and the control group.

Others have employed color Doppler ultrasonography (Veneziano et al, 1995) and automated computer analysis (de la Rosette et al, 1995) in an attempt to improve the value of transrectal ultrasonography in the evaluation of prostatitis patients; however, the results are not conclusive enough to indicate that this is a clinically useful tool.

Transrectal ultrasonography can be valuable in diagnosing medial prostatic cysts in patients with prostatitis-like symptoms (Dik et al, 1996), diagnosing and draining prostatic abscesses (Granados et al, 1992), or diagnosing and draining obstructed seminal vesicles (Littrup et al, 1988). It is not required in all cases of acute bacterial prostatitis but rather only in those patients in whom appropriate antimicrobial therapy is failing (Horcajada et al, 2003).

Transabdominal (Khorasani et al, 2012) and pelvic floor (Davis et al, 2011) ultrasound have been suggested as modalities that could be used in assessing pelvic floor mobility; however, their use has not been standardized to a point at which it could be recommended in clinical practice.

Prostate Biopsy

Occasionally, because of an elevated PSA level or abnormal digital rectal examination findings, prostate biopsy is indicated (Kawakami et al, 2004). Some clinicians will consider starting patients with elevated screening PSA levels and a history of prostatitis or symptoms of CPPS on antibiotics, but this practice is reasonable only in patients with acute or chronic bacterial prostatitis (Nickel, 2002e), conditions that invariably lead to elevated PSA levels. The diagnosis of CP/CPPS should be used only as a reason against a prostate biopsy if the clinician is looking for an excuse not to perform a biopsy (Nickel, 2002e). Antimicrobial or anti-inflammatory treatment of category IV asymptomatic prostatitis detected on biopsy in men with elevated PSA is controversial, and no evidence-based recommendations can be made. Reviews on PSA and prostatitis are available (Kawakami et al, 2004, Hochreiter, 2008, Sandhu, 2009).

Out of desperation, urologists sometimes resort to prostate biopsy in an attempt either to demonstrate histologic evidence of prostatic inflammation or to culture an organism that cannot be cultured with the standard approach. The importance and interpretation of prostate biopsies in prostatitis performed for reasons other than prostate cancer screening are unclear. Doble and associates (1990) demonstrated immune complexes in the prostates of patients with prostatitis but found culture of the prostatic tissue unhelpful (Doble et al, 1989a). Nickel and Costerton (1993) were able to confirm the presence of potentially uropathogenic bacteria in patients with a documented history of chronic bacterial prostatitis in which EPS cultures became sterile after antibiotic therapy. Berger and associates (1997) also confirmed the presence of potential uropathogenic bacteria in prostate biopsy specimens (which correlated to some extent with prostatic inflammation in EPS) in patients in whom the same bacteria did not grow in standard prostatic specimens (e.g., EPS). Krieger and colleagues (1996b) demonstrated the possible presence of microorganisms in the prostate glands of a majority of men with CP syndrome through use of the molecular biologic technique of PCR. At this time, histologic, culture, and molecular biologic evaluations of prostate biopsy specimens in patients with CP/CPPS remain research tools only.

Evaluation of Suspected Seminal Vesiculitis

Occasionally, seminal vesiculitis can occur as a consequence of local bacterial infection in acute and chronic bacterial prostatitis (Zeitlin, 1999), and patients can develop seminal vesicle abscesses (Stearns, 1963; Kennelly and Oesterling, 1989). Seminal vesicle abscesses were traditionally diagnosed clinically by a positive ejaculate culture and seminal vesiculography (Dunnick et al, 1982; Baert et al, 1986) but are now imaged with computed tomography (Patel and Wilbur, 1987), transrectal ultrasonography (Littrup et al, 1988), magnetic resonance imaging (MRI) (Sue et al, 1989), or recently with

technetium-99m ciprofloxacin radioisotope scan (Choe et al, 2003).

Other Potential Markers

Wishnow and associates (1982) found that control patients (10 patients) and men with chronic abacterial prostatitis (4 patients) had no antibodies to gram-negative bacterial antigens, in contrast to men with bacterial prostatitis (6 patients). They hypothesized that immunologic analysis may provide a better diagnostic tool than culturing and microscopy. Shortliffe and coworkers (1981a, 1981b, 1986, 1989, 1992) found that the total IgA and IgG levels in the prostatic fluid in men with chronic abacterial prostatitis were higher than those in controls. They also discovered that prostatic fluid from control or abacterial prostatitis patients did not contain specific antibodies to gram-negative urinary pathogens (in contrast to men with bacterial prostatitis). Nickel and colleagues (2001b) used a similar antibody screening procedure in evaluation of 102 men with CP/CPPS who were subsequently treated with quinolone antibiotics. However, "antibody-positive" patients did not have a better response to antibiotic therapy than "antibody-negative" patients after 12 weeks of therapy. Li and associates (2001) demonstrated increased endotoxin concentrations in EPS and VB3 of men with bacterial prostatitis and inflammatory category IIIA CPPS and suggested that endotoxin levels might be used to identify these categories of patients with CP.

Alexander and colleagues (1998) discovered that men with chronic abacterial prostatitis had higher mean levels of the pro-inflammatory cytokines IL-1 α and TNF- α in seminal plasma compared with controls. Ruggieri and coworkers (2000) noted that levels of both IL-1 α and IL-8 were significantly higher in semen in category IIIA patients (leukocytes) than in category IIIB patients, but there was no statistically significant difference in levels of TNF- α , IL-1 α , or IL-6. This group found no correlation between cytokine levels and the number of leukocytes in EPS. The increased IL-8 levels in the semen of patients with prostatitis symptoms was confirmed by Khadra and coworkers (2006) and Penna and associates (2007), suggesting that this could be a surrogate marker for CP/CPPS. Nadler and colleagues (2000) found that mean levels of IL-1 α in EPS were higher in men with inflammatory chronic abacterial prostatitis and noninflammatory chronic bacterial prostatitis compared with controls. Hochreiter and associates (2000a) did find a direct significant correlation between the number of leukocytes in EPS and IL-1 α levels in EPS. One of the most intriguing possible biomarkers includes monocyte chemoattractant protein-1 and macrophage inflammatory protein-1 α detected in EPS. Both of these chemokines are elevated in category IIIA and IIIB CP/CPPS, and macrophage inflammatory protein-1 α may be a further marker for clinical pain in these patients (Desireddi et al, 2008). The sensitivity, specificity, and, more important, the clinical applicability of all these immunologic tests is really unknown, and none of them is yet indicated in clinical practice.

Marmar and associates (1980) hypothesized that zinc levels in EPS would be a useful marker for prostatitis and found that, indeed, zinc levels in men with chronic abacterial prostatitis and bacterial prostatitis were significantly lower than zinc levels in control patients and men with prostatodynia. However, Zaichick and colleagues (1996) found no differences in zinc levels between patients with chronic abacterial prostatitis, those with BPH, and controls. At this time the measurement of zinc levels in prostatic or semen specimens is clinically unhelpful.

Tanner and associates (1999) detected positive signals (rRNA-based molecular technique with prostatic fluid) in 65% of patients with CP. The condition of 7 of 11 patients with bacterial signals but none of 6 patients without bacterial signals was improved on antibiotic therapy. The same group (Shoskes and Shahed, 2000) subsequently confirmed this finding with a larger cohort of patients. These results are intriguing, and controlled studies evaluating the potential clinical significance of differentiating patients based on molecular biologic techniques are required.

An Approach to Diagnosis and Classification

A diagnostic algorithm that provides a practical approach to the workup of the majority of men with CP/CPPS is shown in Figure 13-7. Box 13-1 shows the tests recently recommended by the ICUD Guidelines for Male LUTS (Nickel et al, 2013b).

Phenotype Assessment in Chronic Prostatitis and Chronic Pelvic Pain Syndrome

Researchers and clinicians have become aware that patients with urologic CPPS, such as CP/CPPS, are not a homogeneous group of patients with identical causative mechanisms, genitourinary pain, urinary symptoms, and/or psychosexual problems but rather a

heterogeneous group of individual patients with widely differing clinical phenotypes. This realization led the NIH to fund the Multidisciplinary Approach to the Study of Chronic Pelvic Pain (MAPP) study group (www.mappnetwork.org) to explore basic science (particularly biomarker and causative studies) and epidemiology to

KEY POINTS: LOWER URINARY TRACT EVALUATION

- Mandatory evaluation includes history-taking, physical examination, urinalysis, and urine culture.
- Recommended evaluation includes lower urinary tract localization test, National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI), sexual functioning assessment, flow rate, residual urine determination, and urine cytology.

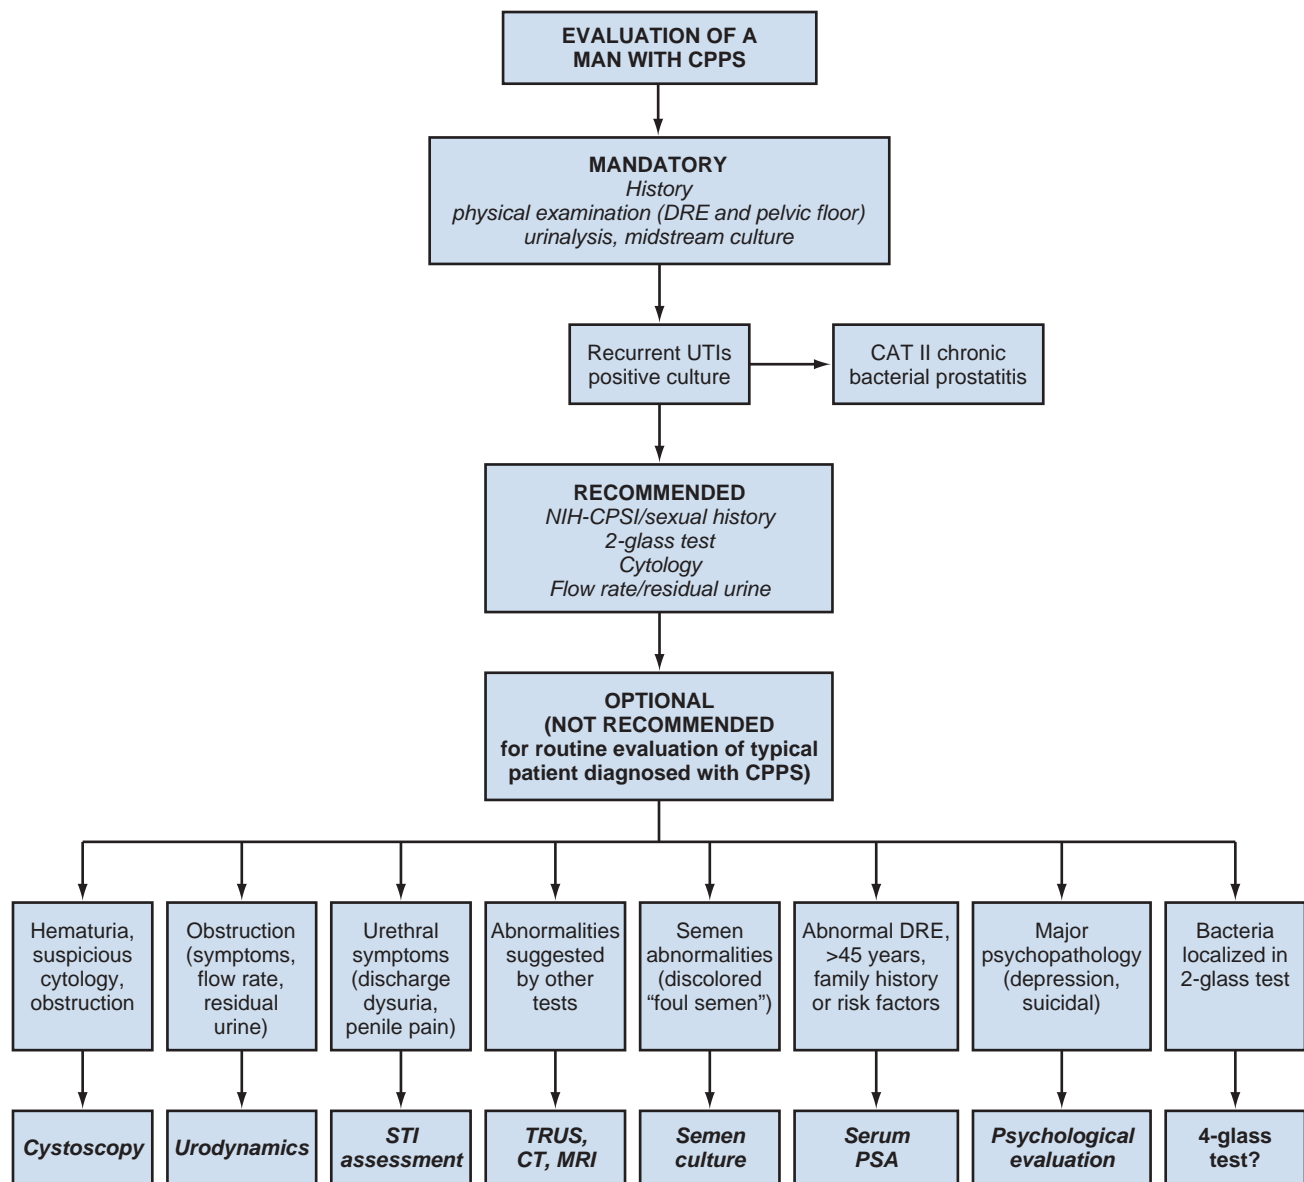

Figure 13-7. A suggested diagnostic algorithm from the 2012 International Consultation on Urological Diseases (ICUD) recommendations for the evaluation of patients with chronic prostatitis and chronic pelvic pain syndrome (CPPS). CAT, category; CT, computed tomography; DRE, digital rectal examination; MRI, magnetic resonance imaging; NIH-CPSI, National Institutes of Health Chronic Prostatitis Symptom Index; PSA, prostate-specific antigen; STI, sexually transmitted infection; TRUS, transrectal ultrasonography; UTIs, urinary tract infections. (Modified from Nickel JC, Wagenlehner F, Pontari M, et al. Male chronic pelvic pain syndrome (CPPS). In: Chapple C, Abrams P, editors. Male lower urinary tract symptoms (LUTS). An International Consultation on Male LUTS, Fukuoka, Japan, Sept 30-Oct 4, 2012. Montreal: Société Internationale d'Urologie (SIU); 2013. p. 331-72.)

BOX 13-1 Evaluation of the Typical Man with Chronic Pelvic Pain Syndrome**MANDATORY**

History
Physical examination, including digital rectal examination and pelvic floor assessment
Urinalysis and culture

RECOMMENDED

Two-glass lower urinary tract evaluation
Symptom inventory or index (National Institutes of Health Chronic Prostatitis Symptom Index [NIH-CPSI])
Sexual functioning assessment (questionnaire)
Flow rate
Residual urine determination
Urine cytology

NOT RECOMMENDED FOR ROUTINE INITIAL EVALUATION*

Four-glass lower urinary tract evaluation
Semen analysis and culture
Sexually transmitted infection evaluation or urethral culture
Pressure-flow studies
Video-urodynamics (including flow-EMG)
Transrectal ultrasound of the prostate
Pelvic imaging—ultrasound, CT scan, MRI
Prostate-specific antigen (PSA)

*Optional in selected patients.

CT, computed tomography; EMG, electromyography; MRI, magnetic resonance imaging.

Modified from Nickel JC, Wagenlehner F, Pontari M, et al. Male chronic pelvic pain syndrome (CPPS). In: Chapple C, Abrams P, editors. Male lower urinary tract symptoms (LUTS). An International Consultation on Male LUTS, Fukuoka, Japan, Sept 30-Oct 4, 2012. Montreal: Société Internationale d'Urologie (SIU); 2013. p. 331–72.

better understand the differences in this very heterogeneous group of patients. It is hoped that “phenotyping” patients may explain our very inconsistent therapeutic results and that the concept eventually may be applicable to direct better management strategies.

In 2009, a clinically practical phenotyping classification system for patients diagnosed with urologic CPPS (CP/CPPS and interstitial cystitis) was proposed (Nickel, 2009; Nickel and Shoskes, 2009; Shoskes et al, 2009a, 2009b). UPOINT is a 6-point clinical classification system that categorizes the phenotype of patients with urologic CPPS into one or more of six clinically identifiable domains: urinary, psychosocial, organ-specific, infection, neurologic/systemic, and tenderness (muscle) (Fig. 13-8). The UPOINT phenotypes can be differentially identified in individual patients through use of the standard clinical assessment described in the previous section and illustrated in Figure 13-7. UPOINT has become a new clinical tool for urologists to use to better understand their patients and direct individually based therapy. UPOINT has been evaluated and validated in female interstitial cystitis (Nickel et al, 2009) and male CP/CPPS (Shoskes et al, 2009a). For CP/CPPS, each domain has been clinically defined with standard clinical assessment, linked to specific mechanisms of symptom production or propagation, and associated with specific therapy (details described in the section on treatment).

In one study researchers determined the phenotype of a cohort of men with documented CP/CPPS through use of the UPOINT system and assessed the frequency of individual domains and their effect on symptom severity (Shoskes et al, 2009a). The percentages of patients positive for each domain were 52%, 34%, 61%, 16%, 37%, and 53% for the urinary, psychosocial, organ-specific, infection, neurologic/systemic, and tenderness domains,

UPOINT: THE “SNOWFLAKE HYPOTHESIS”

Figure 13-8. The UPOINT phenotypic classification system has six clinically defined domains (urinary, psychosocial, organ-specific, infection, neurologic/systemic, and tenderness). Because each individual patient has a unique phenotype, the six-point UPOINT system has been called the “snowflake hypothesis.”

respectively. Only 22% were positive for only one domain, and a significant stepwise increase was found in the total CPSI score as the number of positive domains increased (in other words, symptom severity was associated with the number of identified domains). As symptom duration increased, so did the number of positive domains (suggesting a phenotype progression). The domains with the most significant effect on symptoms included the urinary, psychosocial, organ-specific, and neurologic/systemic domains. For pain, the psychosocial, neurologic/systemic, and tenderness domains had significantly greater scores, whereas only the psychosocial and neurologic/systemic domains influenced the patients’ quality of life. This suggests that domains active outside the pelvis may have the most profound effect on symptoms and quality of life. Further evaluation of CP/CPPS patients (Samplaski et al, 2012) suggests clustering of domains specific to the pelvis (urinary, organ-specific, and tenderness) versus systemic domains (neurologic, infection, and psychosocial). This perspective implies two patient populations that may differ in pathophysiology and treatment response. It is postulated that identifying and managing these phenotypic domains may result in more effective amelioration of CP/CPPS symptoms and greater improvement in quality of life (Nickel, 2009; Nickel and Shoskes, 2009). Since this system was described, numerous investigators have assessed its implications (Hedelin, 2009; Magri et al, 2010; Samplaski et al, 2012) and suggested modifications (Hedelin, 2009; Davis et al, 2013a), including the inclusion of a sexual dysfunction (UPOINT“s”) phenotype (Magri et al, 2010; Davis et al, 2013b), although this addition has been contested by some researchers (Samplaski et al, 2011). This phenotype classification system has been used in English (Shoskes et al, 2009a, 2009b), German (Magri et al, 2010), Italian (Magri et al, 2010), Swedish (Hedelin, 2009), and Chinese (Liu et al, 2012; Zhao et al, 2013), and in each language and culture it has proved to be a useful clinical tool. Updated Canadian, European, and International guidelines for the management of CP/CPPS (Nickel, 2011; Engeler et al, 2013; Nickel et al, 2013b) have recommended that patients be clinically phenotyped during evaluation and treated according to individual phenotypes identified. This phenotype-directed therapy is discussed in the treatment section. My colleagues and I are currently testing specific questionnaires that will provide urologists with a clinical instrument to identify the six major phenotypes and also the further subclassifications that will likely be relevant within each specific domain. A better understanding of cause, mechanisms of disease, and disease progression and the discovery of specific biomarkers (e.g., from the NIH MAPP study) that will allow better phenotype identification will further improve our understanding and management of CP/CPPS.

KEY POINTS: PHENOTYPIC CLASSIFICATION OF CHRONIC PROSTATITIS AND CHRONIC PELVIC PAIN SYNDROME

- UPOINT classification of chronic prostatitis and chronic pelvic pain syndrome patients allows better descriptions of individual phenotypes.

Treatment

This section presents the rationale for each of the various treatments advocated for the prostatitis syndromes and reviews the clinical trial data that support (or not) the use of those specific therapeutic modalities in clinical practice. Recent rigorous prospective studies in chronic bacterial prostatitis and randomized placebo-controlled trials employing standardized definitions and validated outcomes in CP/CPPS have allowed us to develop best-evidence-based treatment strategies in a therapeutic field that used to be based on poor clinical data, dogma, and anecdotal experience (McNaughton Collins et al, 2000b, 2001a; Nickel, 2002c, 2002d, 2004; Schaeffer, 2006; Nickel, 2008b; Anothaisintawe et al, 2011; Nickel, 2011; Cohen et al, 2012; Thakkinstian et al, 2012; Engeler et al, 2013; Nickel et al, 2013b) (Tables 13-2 and 13-3).

Antimicrobials

Rationale. It is generally accepted that acute and chronic bacterial prostatitis are directly related to bacterial infection of the prostate gland. Many urologists further believe that, although bacteria are cultured in only 5% to 10% of cases of prostatitis, bacteria may be the cause of CP symptoms in a significant percentage of patients with this syndrome. Antimicrobial therapy is the most commonly prescribed treatment for the CP syndromes (Moon, 1997; Nickel et al, 1998a; McNaughton Collins et al, 2000b, 2001a; Taylor et al, 2008), independent of culture status.

Pharmacology and Pharmacokinetics. Most antimicrobial pharmacokinetic studies were performed in animal models (dogs and rats) (Madsen et al, 1978; Nickel, 1997b). Stamey (1980) and Stamey and associates (1970) found that acid antibiotic drugs can be detected in prostatic secretions only in very low concentrations, even when plasma concentrations of the drug are very high. Alkaline antibiotic drugs are found in concentrations greater than the simultaneous plasma levels. This phenomenon of ion trapping, and the fact that drug penetration was believed to be a passive transport mechanism based on diffusion and concentration, suggested that drug penetration is dependent on the lipid solubility, degree of ionization, degree of protein binding, and size and shape of the antimicrobial molecule. In dogs, the pH of plasma was found to be 7.4, whereas that of prostatic secretion is 6.4. Therefore, in this model, weak acids (low pKa) concentrate on the plasma side, whereas antibiotics with a higher pKa (weak bases) concentrate in the prostatic secretion.

Because infection may alter the local prostatic environment, thus changing the pharmacokinetic parameters, animal models were developed that introduced infection into the process (Baumueller and Madsen, 1977; Madsen et al, 1994; Nickel et al, 1995). All these animal studies (with and without infection) showed that trimethoprim concentrates in prostatic secretion and prostatic interstitial fluid (exceeding plasma levels), whereas sulfamethoxazole and ampicillin do not. The fluoroquinolones, which are neither pure acids nor bases but have characteristics of both, being zwitterionic drugs (i.e., those that have two pKa values) (Gasser et al, 1986), should allow drug concentration in the prostate at various pH ranges. Carbenicillin and the aminoglycosides did not concentrate in prostatic fluid in dog models.

It is difficult to extrapolate the animal pharmacokinetic studies to humans (Sharer and Fair, 1982). Fair and Cordonnier (1978) found that the prostatic secretion of normal men is

slightly alkaline (pH of approximately 7.3) but also that the pH of prostatic secretion in men with prostatic infection is markedly increased (pH of approximately 8.3). This has been confirmed in other studies (Anderson and Fair, 1976; Blacklock and Beavis, 1978; Pfau et al, 1978), and because the pH gradient is crucial to ion trapping, the results from animal studies should not be applied directly to humans. Unfortunately, drug diffusion studies are difficult to perform in humans, and most studies determine antibiotic concentrations in transurethraly resected BPH adenomas. These studies are further complicated because the high drug concentrations in urine can substantially alter the results. Employing a method to reduce urine contamination, Naber and Madsen (1999) demonstrated that for most fluoroquinolones the ratio of concentrations in prostatic fluid to concentrations in plasma is less than 1 (norfloxacin ratio 0.12, ciprofloxacin ratio 0.18 to 0.26, lomefloxacin ratio 0.48). Concentrations in seminal fluid usually exceed corresponding plasma concentrations of ciprofloxacin and ofloxacin, with ciprofloxacin demonstrating the highest ratio of seminal fluid to plasma (Naber, 1999). The numerous studies evaluating fluoroquinolone concentrations in prostatic tissue demonstrated that the fluoroquinolone concentration in the adenoma tissue is usually higher than that in plasma.

Clinical Trial Data. Unless the patient has a significant anatomic abnormality of the lower urinary tract or develops a prostate abscess, antimicrobial therapy is universally successful in eradicating the bacteria and curing the patient with acute bacterial prostatitis (Nickel and Moon, 2005). In the acutely inflamed prostate gland the pharmacokinetic considerations described in the previous section probably do not play a significant role in antibiotic penetration, and it is believed that most antibiotics achieve reasonable intraprostatic concentrations in the acute phase of the disease. Although prospective clinical trial data are unavailable, most experts suggest therapy initially with parenteral antibiotics (depending on the seriousness of the infection) followed by oral antibiotics with wide-spectrum antimicrobial activity (Becopoulos et al, 1990). The most common drugs suggested for initial therapy (Neal, 1999; Benway and Moon, 2008; Ludwig, 2008) are a combination of penicillin (i.e., ampicillin) and an aminoglycoside (i.e., gentamicin), second- or third-generation cephalosporins, or one of the fluoroquinolones. This traditional approach has changed recently because of the increasing risk of post-prostate biopsy prostate infection with ESBL microorganisms (Ozden et al, 2009; Oh et al, 2013). There are now identified risk factors for this shift, one of which is previous exposure to fluoroquinolones (Mosharafa et al, 2011; Ekici et al, 2012). Both the microorganisms (Bang et al, 2013) and the longer, more difficult clinical treatment course of the prostatitis after urologic intervention (Kim et al, 2012) illustrate the differences with spontaneous acute prostatitis. In patients with acute prostatitis with ESBL or suspected ESBL organisms (usually associated with transrectal prostate biopsies), treatment with a carbapenem (ertapenem, imipenem, or meropenem), amikacin, or colistin for at least 10 to 14 days is recommended (Paterson and Bonomo, 2005; Pallett and Hand, 2010; Fournier et al, 2013). Once the acute infection has settled down, therapy should be continued with one of the oral antimicrobial agents appropriate for the treatment of chronic bacterial prostatitis (e.g., trimethoprim or fluoroquinolones or ESBL-effective antimicrobial therapy based on sensitivity analysis). The duration of optimal therapy is unknown; between 2 and 4 weeks has been suggested (Bjerklund Johansen et al, 1998; Nickel, 1998a; Wagenlehner et al, 2007; Ludwig, 2008). It has been suggested that ineffective treatment of acute bacterial prostatitis may lead to the emergence of a CP category (Rudick et al, 2011; Galeone et al, 2013), particularly if the organism was post-prostate biopsy ESBL *E. coli* (Oh et al, 2013).

In the 1970s to 1990s the most commonly used antimicrobial agents in the treatment of CP were trimethoprim-sulfamethoxazole (co-trimoxazole) (Moon, 1997; Nickel et al, 1998a) and, to a lesser extent, trimethoprim alone. In patients with chronic bacterial prostatitis, eradication of pathogens (the only objective

†Statistically significant difference between groups.

Except for the well-studied fluoroquinolones, most antibiotics (including minocycline, cephalexin, and carbenicillin) do not demonstrate significant clinical efficacy in clinical studies in which patients were observed for sufficient time (Paulson and White, 1978; Oliveri et al, 1979; Mobley, 1981). One notable exception has been the macrolides erythromycin (Mobley, 1974), azithromycin (Skerk et al, 2003), and clarithromycin (Skerk et al, 2002b), particularly when *C. trachomatis* is implicated. A recent Cochrane review (Perletti et al, 2013) concluded that although the microbiologic and clinical cure rates were higher for the macrolides compared with fluoroquinolones for the treatment of intracellular pathogens (*Chlamydia* or *Mycoplasma*), there was no significant difference between azithromycin and clarithromycin.

The fluoroquinolones have demonstrated improved therapeutic results, especially in prostatitis caused by *E. coli* and other members of the Enterobacteriaceae but not necessarily in prostatitis caused by *P. aeruginosa* or enterococci. Naber (1999) analyzed the many studies available in the literature evaluating fluoroquinolones in the treatment of CP and found eight comparable studies in which the diagnosis was obtained by localization studies and in which the patients were observed for a sufficient time after completion of therapy (Weidner et al, 1987; Pust et al, 1989; Heidler, 1990; Schaeffer and Darras, 1990; Pfau, 1991; Weidner et al, 1991a; Ramirez et al, 1994; Koff, 1996); in these studies the researchers evaluated norfloxacin, ciprofloxacin, ofloxacin, and lomefloxacin. In 2005, Naber, reporting at the Sixth International Consultation on New Developments in Prostate Cancer and Prostate Disease, Paris, June, 2005 (Schaeffer et al, 2006), added three more recent studies that met these strict criteria (Naber et al, 2000; Naber and European Lomefloxacin Prostatitis Study Group, 2002; Bunderick et al, 2003) with a further addition from 2008 (Naber et al, 2008). The overall conclusion was that fluoroquinolones were the optimal antimicrobial agent for the treatment of chronic bacterial prostatitis. In a 2013 Cochrane review, Perletti and colleagues (2013) undertook an ambitious comprehensive review of antimicrobial therapy for chronic bacterial prostatitis by evaluating and comparing 18 clinical trials (Smith et al, 1979; Paulson et al, 1986; Cox, 1989; Ohkawa et al, 1993b; Koff 1996; Bustillo et al, 1997; Naber and European Lomefloxacin Prostatitis Study Group, 2002; Skerk et al, 2002a, 2002b; Bunderick et al, 2003; Skerk et al, 2003, 2004a, 2004b, 2006; Giannarini et al, 2007; Aliaev et al, 2008; Cai et al, 2009, 2010; Zhang et al, 2012) that met strict inclusion criteria including standardized microbiologic diagnoses and outcomes (microbiologic and clinical) in randomized controlled studies in which the comparison was with placebo, different administration schedules, or another antibiotic or combinations of antibiotics plus

other agents. The authors concluded that there are no significant differences in microbiologic and clinical efficacy or in adverse effect rates among the oral fluoroquinolones ciprofloxacin, levofloxacin, lomefloxacin, ofloxacin, and prulifloxacin. As mentioned previously, the macrolides appear to be superior to the fluoroquinolones for the treatment of proven chlamydial infection. The authors further concluded that there is inconclusive randomized controlled evidence regarding the role of combination treatments of chronic bacterial prostatitis with antimicrobial and nonantimicrobial substances, such as phosphodiesterase-5 inhibitors or herbal preparations.

For CP caused by *E. coli*, treatment duration of 1 month for the fluoroquinolones seems to be superior to the usual 3-month treatment with trimethoprim-sulfamethoxazole. It has been suggested that antibiotics should be continued only for 4 to 6 weeks if pre-treatment cultures are positive and/or the patient has reported positive effects from treatment (Wagenlehner et al, 2007); however, the duration of therapy cannot be confirmed from analysis of available studies (Perletti et al, 2013). Some clinicians have observed that as many as 20% of patients in whom an initial treatment period fails could be rescued with a second cycle of treatment with another antibiotic (Magri et al, 2007b). In microbiologically diagnosed chronic bacterial prostatitis, eradication of bacteria is associated with both short-term and long-term clinical success (Nickel and Xiang, 2008). This appears to be true in men with recent onset of prostatitis associated with bacterial localization with the traditional uropathogens (gram-negative uropathogens and *Enterococcus* species) as well as nontraditional bacteria (gram-positive bacteria such as coagulase-negative staphylococcal and streptococcal species) (Magri et al, 2007a; Nickel and Xiang, 2008). A number of investigators (Baert and Leonard, 1988; Jimenez-Cruz et al, 1988; Yamamoto et al, 1996; Guercini et al, 2005b) have advocated direct injection of antibiotics into the prostate gland, but this method has never been rigorously evaluated or become popular among urologists. It appears that men with chronic bacterial prostatitis and prostatic calculi are more difficult to cure (Zhao et al, 2012). Many physicians have resorted to prolonged therapy with low-dose prophylactic or suppressive antimicrobials for recurrent or refractory prostatitis, respectively, although this practice has not been confirmed with clinical studies.

Many studies evaluating physicians' practice patterns in prostatitis syndromes (de la Rosette et al, 1992a; Moon, 1997; Collins et al, 1998; Nickel et al, 1998a; McNaughton Collins et al, 2000a; Taylor et al, 2008) have confirmed that most patients diagnosed with CP, irrespective of culture results, are treated with antimicrobial therapy. Older studies have generally indicated that approximately 40% of patients with nonbacterial CP have some symptomatic

improvement with antimicrobial therapy (Berger et al, 1989; Weidner, 1992; de la Rosette et al, 1993a; Ohkawa et al, 1993b; Bergman, 1994; Bjerklund Johansen et al, 1998; Tanner et al, 1999; Nickel et al, 2001b). Antibiotic therapy may benefit CP/CPPS patients by three different mechanisms: a strong placebo effect, the eradication or suppression of noncultured microorganisms (Nickel et al, 2001b), or the independent anti-inflammatory effect of some antibiotics (Yoshimura et al, 1996; Galley et al, 1997). It has been suggested by a European consensus group evaluating the role of antibiotics in the treatment of CP (Bjerklund Johansen et al, 1998; Engeler et al, 2013) that antibiotics could be considered empirical treatment for category IIIA CP/CPPS, but the benefits should be appraised after a minimum of 2 to 4 weeks of therapy. The antibiotics could be continued for 4 to 6 weeks if the patient reports positive effects from treatment (Wagenlehner et al, 2007). These recommendations remain controversial (Taylor et al, 2008), particularly because new data appear to provide conflicting interpretations. Two multicenter randomized placebo-controlled studies have assessed the efficacy of 6 weeks of levofloxacin (Nickel et al, 2003b) and ciprofloxacin (Alexander et al, 2004) in men with CP/CPPS. In these trials the participants had chronic symptoms for a long duration (many years) and had been heavily treated (including treatment with antibiotics). In the study by Nickel and associates (2003b) 80 patients were randomized to levofloxacin or placebo, whereas in the NIH-sponsored study reported by Alexander and colleagues (2004) 196 men with CP/CPPS were randomized in a 2 × 2 factorial design to ciprofloxacin, tamsulosin, the combination of ciprofloxacin and tamsulosin, or placebo. In both of these prospective-designed controlled multicenter trials, no significant difference was reported between the fluoroquinolone and placebo in terms of symptom amelioration. **Antibiotics should not be prescribed for previously treated men with CP/CPPS of long duration.** However, two prospective trials comparing the effect of 4 to 6 weeks of antibiotics (Magri et al, 2007a; Nickel and Xiang, 2008) in men with localization of both traditional uropathogens and organisms not usually believed to be uropathogenic (and therefore classified as category III CP/CPPS) showed similar eradication and clinical success rates (75% to 80%). Furthermore, in the study by Nickel and Xiang (2008), the eradication of those organisms, whether or not they were considered to be uropathogens, correlated with both short- and long-term clinical success. Because the majority of patients in Nickel and Xiang's study (2008) had a short history of prostatitis and were antibiotic naive for that episode, it was concluded that **antibiotic treatment may be considered for antibiotic-naive patients with a recent diagnosis of prostatitis, regardless of culture status.**

α-Adrenergic Blocker Therapy

Rationale. Patients with CP/CPPS have significant lower urinary tract symptoms, which appear to be related to poor relaxation of the bladder neck during voiding (Barbalias et al, 1983; Murnaghan and Millard, 1984; Blacklock, 1986; Hellstrom et al, 1987; Barbalias, 1990; Kaplan et al, 1997). The subsequent turbulent "dysfunctional" voiding may predispose the patient to reflux of urine into the prostatic ducts, causing intraprostatic inflammation and subsequently pain (Kirby et al, 1982). **The bladder neck and prostate are rich in α receptors, and it is hypothesized that α-adrenergic blockade may improve outflow obstruction, improving urinary flow and perhaps diminishing intraprostatic ductal reflux.**

Clinical Trial Data. A number of older clinical trials suggested that the α-adrenergic blockers diphenoxylbenzamine (Dunzendorfer, 1983), phenoxybenzamine (Osborn et al, 1981), alfuzosin (de la Rosette et al, 1992c; Barbalias et al, 1998), terazosin (Neal and Moon, 1994; Barbalias et al, 1998; Lacquaniti et al, 1999; Gül et al, 2001), doxazosin (Evliyaoglu and Burgut, 2002), and tamsulosin (Lacquaniti et al, 1999) resulted in significant symptomatic improvement of prostatitis-related symptoms; however, these trials were small, most were uncontrolled, and outcome measures were not validated. Studies by Barbalias and associates (1998) and Youn et al (2008) further seemed to indicate that the combination of

antibiotics and α-adrenergic blockers improved the clinical result in patients with chronic bacterial prostatitis.

At least six randomized placebo-controlled trials with clearly defined CP/CPPS patients (NIH classification) and employing the NIH-CPSI as the outcome parameter appear to have confirmed the efficacy of α-adrenergic blockers but only in men who have recent-onset disease and have not been heavily pretreated and who are on therapy for longer than 6 weeks. Cheah and colleagues (2003b) randomized 86 patients with CP to either terazosin or placebo for 14 weeks. Patients on terazosin had a 50% reduction in mean symptom score compared with 37% in the placebo-treated group. Terazosin resulted in modest but significant improvement in all domains of the NIH-CPSI. Mehik and colleagues (2003) followed 19 patients randomized to 6 months of alfuzosin treatment and 20 patients on 6 months of placebo therapy, and both groups were followed for a further 6 months after discontinuing the active or placebo medication. Patients in the alfuzosin group had a significant amelioration of symptoms compared with the placebo therapy group that was evident at 4 months and became even more clinically significant by 6 months. At 6 months, 65% of alfuzosin patients were rated as responders compared with 24% of the placebo group. The beneficial effect appeared to wear off over the next 6 months after the alfuzosin was discontinued. Nickel and colleagues (2004c) randomized 57 men with CP/CPPS to tamsulosin, 0.4 mg, or placebo after a 2-week placebo run-in and observed the two groups for 6 weeks. Patients treated with tamsulosin had a statistically significant (but only modest clinically significant) treatment effect compared with patients taking a placebo. A significant treatment effect was not observed in patients who had mild symptoms, but patients with severe symptoms (75th percentile) had a statistically and clinically significant response compared with placebo. It appears that the response to α-adrenergic blockers is durable, for at least up to 24 to 38 weeks as long as the patient stays on the medication (Mehik et al, 2003; Cheah et al, 2004). Another study (Tugcu et al, 2007) included 90 treatment-naive patients with CP/CPPS randomized to receive doxazosin, 4 mg/day, alone or a triple therapy (doxazosin, 4 mg/day, plus an anti-inflammatory agent—ibuprofen, 400 mg/day—and a myorelaxant—thiocolchicoside, 12 mg/day) or placebo. Over 6 months, the total NIH-CPSI score significantly improved in the doxazosin group (from 23.1 to 10.5 points) and triple-therapy groups (from 21.9 to 9.2), and it remained stable in the placebo group (from 22.9 to 21.9). Chen and colleagues (2011) examined a total of 100 men diagnosed with CP/CPPS randomly allocated to receive either 0.2 mg of tamsulosin daily or placebo for 6 months. The tamsulosin patients had modest satisfactory improvements compared with the placebo group during treatment. Six months after initiation of treatment, the mean decrements of total NIH-CPSI score in the tamsulosin and placebo groups were 7.5 ± 1.9 and 4.0 ± 2.3, respectively ($P < .01$). After cessation of therapy, the significant difference waned gradually. Two years after cessation of therapy, the mean decrements in total NIH-CPSI score in the two groups were 3.0 ± 1.3 and 1.9 ± 0.9, respectively ($P > .05$). This suggests that in patients who respond to α blockers, the therapy must be continued long term. Finally, Nickel and coworkers (2011a) evaluated the efficacy and safety of two doses of silodosin versus placebo in 151 men with CP/CPPS who had not been treated previously with α blockers. Patients randomized to silodosin 4 mg experienced a significant decrease in total NIH-CPSI of −12.1 versus placebo (−8.5). At this dose, men also had a significant decrease in the urinary and quality of life subscore as well as the physical component of the Medical Outcomes Study Short Form 12 quality-of-life assessment. During global response assessment 56% of patients receiving 4 mg of silodosin versus 29% receiving placebo reported moderate or marked improvement (also significant). Increasing the dose of silodosin to 8 mg resulted in no incremental treatment effects.

In contrast, the results from the NIH CPCRN randomized controlled trial (Alexander et al, 2004) comparing 6 weeks of ciprofloxacin, tamsulosin, and the combination of ciprofloxacin and tamsulosin with placebo in very chronic and heavily pretreated patients failed to show any improvement in patients

treated with tamsulosin (with or without ciprofloxacin) compared with patients treated with placebo. A number of meta-analyses and comprehensive reviews of these data have suggested that α -adrenergic blockers provide significant symptom amelioration only after more than 6 weeks of therapy in less heavily treated patients with recent onset of moderate to severe symptoms (Yang et al, 2006; Mishra et al, 2007; Nickel, 2008a). To test this hypothesis, an NIH multicenter, randomized, double-blind, placebo-controlled trial was conducted to evaluate the efficacy of 12 weeks of alfuzosin or placebo to reduce symptoms in 272 randomized men with CP/CPPS diagnosed within 2 years previously and who had not been previously treated with an α -adrenergic blocker (Nickel et al, 2008a). The rate of the primary outcome (reduction of at least 4 points in NIH-CPSI total score from baseline) was 49% in both treatment groups. The response rates at 12 weeks measured with a global response assessment were also similar: 34% and 35% for the placebo and alfuzosin groups, respectively ($P = .90$). These important findings did not support the use of α -adrenergic blockers in recently diagnosed α -adrenergic blocker-naïve men with CP/CPPS.

Anti-Inflammatory Agents and Immune Modulators

Rationale. Prostatic inflammation is associated with category IIIA CP/CPPS, and elevated cytokine levels are noted in the semen (Alexander et al, 1998; Ruggieri et al, 2000) and EPS (Hochreiter et al, 2000b; Nadler et al, 2000) of patients with inflammatory CPPS. Nonsteroidal anti-inflammatory drugs, corticosteroids, and immunosuppressive drugs theoretically should improve the inflammatory parameters within the prostate and possibly result in a reduction of symptoms (Pontari, 2002).

Clinical Trial Data. Canale and associates (1993a) found that nimesulide (a nonsteroidal anti-inflammatory drug) quickly reduced inflammatory-type symptoms such as dysuria, strangury, and painful ejaculation. A second study by Canale and colleagues (1993b) found that, by the rectal route, ketoprofen was inferior to nimesulide (both drugs were used as suppositories). Prednisolone has been suggested as a potent anti-inflammatory for CP (Bates and Talbot, 2000), and a randomized study presented by Dimitrakov and associates (2004) indicates that high-dose methylprednisolone (followed by rapid tapering of dose) may have more efficacy than placebo, even after 12 months, but the side effect profile makes this type of therapy less attractive. A small randomized trial evaluating oral corticosteroids did not show superiority of the active therapy over placebo (Bates et al, 2007).

The new class of cyclooxygenase-2 inhibitors has proved successful for long-term treatment of other chronic inflammatory conditions such as rheumatoid arthritis and chronic osteoarthritis; many urologists have employed these medications for prostatitis patients, with some anecdotal successes reported. The results of a North American randomized controlled trial comparing the cyclooxygenase-2 inhibitor rofecoxib with placebo indicated that many men with CPPS benefited (in terms of pain and quality of life) from rofecoxib therapy compared with placebo. In this study, in which 161 patients were randomized to rofecoxib 25 mg, rofecoxib 50 mg, or placebo, only patients on the high dose showed any clinical improvement compared with the placebo. Very few patients, however, had complete resolution of their symptoms (Nickel et al, 2003c). Another study from China (Zeng et al, 2004) assessing the effectiveness of two doses of the cyclooxygenase-2 inhibitor celecoxib also demonstrated a dose-dependent response (200 mg twice a day for 6 weeks was more effective than 200 mg once a day). Zhao et al (2009) randomized 64 patients with category IIIA CPPS to celecoxib (200 mg daily) and placebo for 6 weeks with 8 weeks of follow-up. These researchers showed that celecoxib provides significant symptomatic improvement, but the benefit was limited to the duration of the therapy. At this time, high-dose, long-duration monotherapy with cyclooxygenase-2 inhibitors is not recommended.

Because the clinical and pathologic characteristics are similar to those of interstitial cystitis and there is evidence that pentosan

polysulfate, a glycosaminoglycan drug that has been used in the treatment of interstitial cystitis and provides significant anti-inflammatory effects (Sunaga et al, 2012), Wedren (1987) compared the efficacy of pentosan polysulfate with placebo. In this small study the treated group was noted to have a statistically significant improvement in symptoms, but the major symptom that improved was nonspecific myalgias and arthralgias. An uncontrolled pilot study evaluating oral pentosan polysulfate in 32 men with CPPS demonstrated amelioration of symptoms and improvement in the quality of life in over 40% after treatment for 6 months (Nickel et al, 2000). The results of a multicenter, randomized, placebo-controlled trial that randomized 100 men to pentosan polysulfate, 900 mg/day (three times the usual dose), or placebo indicated this medication provided modest benefit for some men with CPPS (Nickel et al, 2005a).

Thalidomide, a cytokine modulating drug, was assessed in 30 men with chronic bacterial prostatitis and abnormal semen cytokine levels (IL-2, IL-6, IL-8, IL-10, and TNF- α) in a randomized placebo-controlled trial (Guercini et al, 2005a). Despite a significant reduction in cytokine levels in semen, no difference in symptom relief was noted. A similar lack of efficacy was noted in a small placebo-controlled trial evaluating the leukotriene antagonist zafirlukast (Goldmeier et al, 2005).

The potential of various anti-inflammatory agents, immune modulators, and cytokine inhibitors makes these classes of drugs potentially useful as adjunctive therapy for the CP syndromes, but clinical trials suggest that they are not a useful monotherapy.

Muscle Relaxants

Rationale. Many investigators believe that CPPS is the ultimate reflection of a smooth and skeletal neuromuscular dysregulatory phenomenon in the perineum or pelvic floor (Osborn et al, 1981; Egan and Krieger, 1997; Anderson, 1999; Zermann and Schmidt, 1999). The use of α blockers to relax smooth muscle (see earlier discussion of α -adrenergic blockers) and skeletal muscle relaxants combined with adjuvant medical and physical therapies has been advocated and promoted (Anderson, 1999; Zermann and Schmidt, 1999).

Clinical Trial Data. In one of the few studies to compare muscle relaxants with placebo, Osborn and associates (1981) conducted a prospective double-blind study comparing phenoxylbenzamine, baclofen (a striated muscle relaxant), and placebo in 27 patients with prostatodynia (category IIIB). Patients were treated with each agent for 1 month in a crossover trial. Symptomatic improvement was seen in 37% of the patients treated with baclofen compared with 8% treated with placebo. Simmons and Thin (1985) compared diazepam with an antibiotic in patients with chronic abacterial prostatitis and found no difference in symptom improvement between the diazepam group (8 of 11 men improved) and the antibiotic group (7 of 12 men improved). Unfortunately these studies were hindered by a lack of controlled and defined entry criteria and no quantified measurement of patients' responses and therefore the role of muscle relaxants has yet to be determined.

Hormone Therapy

Rationale. Prostate growth and function are influenced by the local hormonal milieu, especially by androgens. Theoretically, anti-androgens (including 5 α -reductase inhibitors) could result in regression of prostatic glandular tissue (inflammation is believed to begin at the level of the ductal epithelium), decreased intraprostatic pressure (Mehik et al, 2002), improved voiding parameters (especially in older patients with BPH and prostatitis), and reduced intraprostatic ductal reflux (Nickel, 1999a).

Clinical Trial Data. Holm and Meyhoff (1996) were the first to note that the 5 α -reductase inhibitor finasteride had potential in alleviating symptoms by observing the effect of finasteride therapy in four patients with CP or prostatodynia. Leskinen and colleagues

(1999) randomized 41 patients with chronic idiopathic prostatitis (i.e., nonbacterial prostatitis and prostatodynia) to treatment with placebo (25%, or 10 patients) or finasteride (75%, or 31 patients) for 1 year. Compared with placebo, finasteride reduced prostatitis and BPH symptom scores; however, there was no statistically significant difference in pain between the two groups. The baseline characteristics of the two groups were not comparable, and the enrolled patients consisted of an unknown mixed population with inflammatory and noninflammatory prostatitis syndromes. A randomized open-label comparative trial in CP/CPPS men showed significantly more improvement in men treated for a year with finasteride compared with saw palmetto, an herbal therapy (Kaplan et al, 2004). A randomized controlled trial compared the reduction of NIH-CPSI in 64 men with CP/CPPS randomized to finasteride or placebo (Nickel et al, 2004b). Six months of finasteride resulted in a numerical but not statistically significant reduction in symptoms compared with the symptom reduction noted in the placebo group. In the 4-year Reduction by Dutasteride of Prostate Cancer Events (REDUCE) prostate cancer reduction trial, dutasteride therapy produced statistically and possibly clinically significant benefits compared with placebo in the men with preexisting prostatitis or prostatitis symptoms (Nickel et al, 2011b). **Finasteride and dutasteride cannot be recommended as a monotherapy except in men with associated BPH.**

Testosterone and dihydrotestosterone are not the only hormones with a possible effect on prostate inflammation; estrogens may also play a role. A number of small, poorly controlled studies (Cavallini, 2001; Saita et al, 2001) suggested that mepartiricin (a drug that lowers estrogen levels in the prostate) may be useful in the treatment of CP/CPPS. A small prospectively designed trial randomized 26 men with CP/CPPS to 60 days of therapy with mepartiricin or placebo (De Rose et al, 2004). The study showed a statistical and perhaps clinically significant benefit (60% vs. 20% improvement, respectively) that should stimulate further research in the role of hormonal manipulation (in this case estrogens) in the treatment of CP/CPPS.

Phytotherapeutic Agents

Rationale. A number of plant extracts have been shown in many in vitro experiments to have 5 α -reductase activity, α -adrenergic blockade activity, effects on bladder contractility, and anti-inflammatory properties (Lowe and Fagelman, 1999; Shoskes, 2002).

Clinical Trial Data. Three specific phytotherapeutic agents have been tested in well-controlled clinical trials: Cernilton, a pollen extract (Buck et al, 1989; Rugendorff et al, 1993; Wagenlehner et al, 2009); Quercetin, a natural bioflavonoid (Shoskes et al, 1999); and *Serenoa repens* (saw palmetto berry) extract (Kaplan et al, 2004; Reissigl et al, 2004). Rugendorff and coworkers (1993) noted that over half of 72 patients with CP without other lower urinary tract abnormalities had favorable improvements in pain and irritative voiding symptoms when treated with Cernilton, but no control group was included in this study. A randomized study of pollen extract (Cernilton) in 122 men with category IIIA CP/CPPS showed that men receiving the active treatment had statistically significant improvements in the pain and quality-of-life components of the CPSI (Wagenlehner et al, 2009). A controlled, randomized study of a similar preparation, Prostat/Poltit (grass pollen extract, including rye pollen), in 60 patients showed greater improvement in patients receiving active therapy compared with placebo, but no validated outcome index was incorporated into the study design (Elist, 2006). Shoskes and associates (1999) randomized 15 patients to the bioflavonoid Quercetin and 13 patients to placebo for 1 month. Sixty-seven percent of the patients in the treatment group were considered responders compared with only 20% of the patients in the placebo arm. Kaplan and associates (2004) noted possible benefits with the use of saw palmetto but did not note any appreciable long-term improvement in any CP/CPPS parameters when compared with 12 months of finasteride in a randomized open-label comparative study. However, Reissigl and colleagues (2004) reported that there

was moderate to marked improvement in more than 60% of 72 CP/CPPS patients after 12 months of therapy with *S. repens* extract compared with less than 25% in the 70 men in the placebo-treated group. However, further follow-up did not support the durability of this therapy (Reissigl et al, 2005). **Phytotherapy for CP/CPPS may look promising, but further multicenter randomized controlled trials with well-characterized, standardized, and stable herbal components should be considered to assess their role in therapy.**

Neuromodulator Therapy

Rationale. One proposed mechanism is that CP/CPPS, particularly chronic, long-standing cases, represents a neurogenic pain syndrome and that the subsequent pain is actually a neuropathic pain (Pontari and Ruggieri, 2004). Patients with CP/CPPS have a history of neurologic disease that is almost five times more likely among cases than control subjects (Pontari et al, 2005), and men with CP/CPPS have been found to have abnormalities of both the afferent and efferent autonomic nervous systems (Yang et al, 2003; Yilmaz et al, 2007; Yang, 2013). This type of neuropathic pain related to CNS sensitization responds to gabapentinoids in other chronic pain conditions (Rosenstock et al, 2004; Crofford et al, 2005).

Clinical Trial Data. A recent NIH CPRN randomized placebo-controlled trial evaluated the effect of the gabapentinoid pregabalin on symptoms of men with long-standing, treatment-refractory CP/CPPS (Pontari et al, 2010). Among the 103 men assigned to pregabalin, 47% reported at least a 6-point decrease in total NIH-CPSI score at 6 weeks (primary end point) compared with 35.8% of 106 men assigned to placebo ($P = .072$). The NIH-CPSI total score decreased by a mean of 6.6 and 4.2 points (of 43) in the pregabalin and placebo groups, respectively ($P = .008$), whereas significantly more men in the pregabalin arm reported they were markedly or moderately improved compared with placebo (31% and 19%, respectively; $P = .023$). Although 6 weeks of pregabalin therapy was not superior to placebo for treating symptoms of CP/CPPS based on the primary end point, the impressive differences in secondary end points suggest that pregabalin may prove effective in some men with long-standing CP/CPPS. A recent well-powered study evaluating tanezumab (Nickel et al, 2012), a humanized monoclonal antibody directed against nerve growth factor, was not able to show significant benefit in a generally unselected population of men with CP/CPPS; however, a signal suggested that it might be beneficial in selected men (perhaps those with expression of nerve growth factor), a concept that should further explored (Watanabe et al, 2011). **It appears that for neuromodulatory therapy to be effective, it will need to be targeted toward a specific patient phenotype; however, biomarkers, either clinically or laboratory derived, have yet to be confirmed.**

Allopurinol

Rationale. Persson and Ronquist (1996) theorized that the intraprostatic ductal reflux of urine increases the concentration of metabolites containing purine and pyrimidine bases in the prostatic ducts, causing inflammation.

Clinical Trial Data. Persson and associates (1996) compared allopurinol therapy with placebo in a double-blind controlled study in 54 men. The allopurinol groups had lower levels of serum urate, urine urate, and EPS urate and xanthine. With variations in accepted statistical methodology, the investigators were able to show a difference in the mean patient-reported discomfort score between the study and the control groups at certain times in this trial with 330 days of follow-up. However, a re-examination of the data with use of more standardized statistical analyses did not convince other groups that changes in the urine and prostatic secretion of purine and pyrimidine bases resulted in significant amelioration of symptoms in this particular trial (Nickel et al, 1996). A follow-up randomized clinical trial further showed no advantage of allopurinol compared with placebo (Ziaee et al, 2006).

Prostatic Massage

Prostatic massage has been the principal therapy for prostatitis since the turn of the 20th century (O'Connor, 1936; Campbell, 1957). With the introduction of the scientific approach advocated by Meares and Stamey in 1968, prostatic massage became important only as a diagnostic tool, but as a therapy it was abandoned by urologists. It eventually regained some popularity, primarily because of the failure of standard medical therapy in patients with refractory symptoms of CP. Its benefits are believed to arise from draining theoretically occluded prostatic ducts and improving circulation and antibiotic penetration (Hennenfent and Feliciano, 1998). Independent but uncontrolled studies (Nickel et al, 1999b; Shoskes and Zeitlin, 1999) found clinical benefits in one third to two thirds of patients treated with repetitive prostatic massage (two to three times per week) for 4 to 6 weeks along with antibiotic therapy. However, another trial indicated that prostatic massage does not significantly improve the response of men with CP/CPPS treated with antibiotics (Ateya et al, 2006). It appears that some patients may improve with prostatic massage, but a panel of North American prostatitis experts (Nickel et al, 1999a) could not come to a consensus on the potential overall benefit or even the mechanism of achievement of that benefit if it does occur. A subsequent systematic review of the literature concluded that evidence for a role of repetitive prostatic massage as an adjunct in the management of CP is at most "soft" but that the practice could be considered as part of multimodal therapy in selected patients (Mishra et al, 2008). It has been suggested that frequent ejaculation may achieve the same function as prostatic massage (Yavascaoglu et al, 1999).

Pelvic Floor Physiotherapy (Including Directed Perineal and/or Pelvic Floor Massage and Myofascial Trigger Point Release)

Most clinicians recognize that men with prostatitis syndromes, especially category III CPPS, have specific anatomic areas that cause discomfort. Anderson (1999) believes that prolonged or chronic tension, distention, or distortion in the muscle bands (e.g., in the perineum) leads to a painful trigger point that is responsible for the pain. Predisposing factors leading to the formation of myofascial trigger points in the perineum or pelvis may include mechanical abnormalities in the hip and lower extremities, chronic urinary holding patterns (dysfunctional toilet training), sexual abuse, repetitive minor trauma, constipation, trauma, unusual sexual activity, recurrent infections or surgery, and perhaps stress and anxiety (Anderson et al, 2009a). Treatment of these trigger points includes heat therapy, physiotherapy massage, ischemic compression, stretching, anesthetic injections, acupuncture, electroneural modulation, and mind-body interactions such as progressive relaxation exercises, yoga, and hypnosis (Potts, 2003). Anderson and associates (2005) report that employing these techniques with a team consisting of a urologist, physiotherapist, and psychologist results in more than half of patients having or demonstrating a clinically detectable improvement. A case study analysis indicates that this may be an effective therapeutic approach in some patients (Anderson et al, 2005) and may result in improvement not just in pain but also in sexual function (Anderson et al, 2006). This technique has been further refined and modified by employing relaxation training (Anderson et al, 2011b). This technique has even been described as self-treatment using a "myofascial trigger point wand" (Anderson et al, 2011a). Certainly, many physicians managing CP/CPPS have found that directed physiotherapy results in significant benefits for selected patients with pelvic floor pathology diagnosed on physical examination (Van Alstyne et al, 2010). An NIH pilot study of men and women with chronic pelvic pain randomized to treatment with either relaxation massage or specific pelvic massage therapy demonstrated improvement; however, the beneficial effects were mainly found in women at 6 months, and the investigators could not corroborate these findings in the 23 randomized men (FitzGerald et al, 2009). In contrast, Marx and coworkers (2009), who randomized 35 men to osteopathic therapy, noted statistically significant

differences in favor of the osteopathy group ($P < .0005$). Long-term follow-up of 19 of the 20 men randomized to the treatment arm continued to show benefits for 5 years (Marx et al, 2013). Most clinicians with experience in the field believe that variations of pelvic floor physiotherapy can be extremely helpful in patients with demonstrable pelvic floor pathology that was found to be refractory to other therapies (Fitzgerald et al, 2013).

Pudendal Nerve Entrapment Therapy

It has been hypothesized that the symptoms of CPPS could be caused by entrapment of the pudendal nerve, perhaps between the sacrotuberous and sacrospinous ligaments, in the canal of Alcock or by the falciform process of the sacrotuberous ligament (Robert et al, 1998). Pudendal nerve blocks (Thoumas et al, 1999; McDonald and Spigos, 2000; Peng and Tumber, 2008) and neurolysis surgery (Robert et al, 1993; Mauillon et al, 1999) have been suggested for treatment. The role of the pudendal nerve in chronic perineal pain deserves more scientific scrutiny.

Biofeedback

It is possible that the voiding and pain symptoms associated with CP/CPPS may be secondary to some form of pseudodysynergia during voiding or repetitive perineal muscle spasm; biofeedback has the potential to improve this process. Kaplan and associates (1997), Nadler (2002), Ye and colleagues (2003), and Cornel and coworkers (2005) have demonstrated in small uncontrolled studies that biofeedback does ameliorate specific prostatitis-like symptoms in some men. Controlled clinical trials will be necessary to evaluate this mode of therapy.

Acupuncture

Acupuncture is an accepted traditional Chinese therapy for chronic pain, including pain from prostatitis (Ge et al, 1988; Katai, 1992; Ikeuchi and Iguchi, 1994). Chen and Nickel (2003) determined in a pilot study of 12 treatment-refractory men that acupuncture was safe and provided effective and durable symptom improvement. A subsequent study comparing 10 weeks of acupuncture versus sham acupuncture treatment indicated that the active acupuncture proved to be almost twice as likely as sham treatment to improve CP/CPPS symptoms (Lee et al, 2008a). A subsequent trial evaluating electroacupuncture versus sham therapy (Lee and Lee, 2009) also confirmed the efficacy of this approach. A 2011 analysis by Lee and associates further confirmed that sham therapy comparison in acupuncture trials was feasible (Lee et al, 2011). A subsequent systemic review (Posadzki et al, 2012) concluded that acupuncture is a reasonable choice of therapy for selected men with CP/CPPS.

Psychological Support

Data from the NIH Prostatitis Cohort (Tripp et al, 2004, 2005, 2006; Nickel et al, 2008c) support a biopsychosocial model that associates the chronic pain and poor quality of life of CP/CPPS with depression and suggest that physicians may be able to advise patients to avoid certain pain coping strategies that can be associated with greater depression. Nickel and colleagues (2008b) have developed an evidence-based cognitive behavioral treatment program for men with CP/CPPS (described in Tripp et al, 2011). This program specifically targets empirically supported biopsychosocial variables (e.g., pain catastrophizing, depressive thinking, social support) and encourages patients to critically evaluate their patterns of thinking and to entertain novel thinking and behavioral responses to their troublesome symptoms, with an end objective to improve overall quality of life. A pilot evaluation of the program demonstrated significant merit in this approach (Tripp et al, 2011).

Studies also show that the maladaptive pain coping technique of employing "pain-contingent resting" (using rest rather than more active behaviors to control pain) is reported by CP/CPPS patients

in response to their pain (Tripp et al, 2006; Nickel et al, 2008c). It was suggested by Tripp and coworkers (2006) that such sedentary behaviors in the presence of pain may be associated with elevated disability in men with CP/CPPS. A double-blind randomized study showed that men participating in aerobic exercise were significantly better than those who were randomized to stretching and motion exercise, suggesting that increased physical activity is a valid option in men with CP/CPPS (Giubilei et al, 2007). The results of a study examining perceived helpfulness of medical and self-management strategies suggested that clinicians may find it useful to support patients' use of safe, inexpensive self-management approaches, such as warm baths, increased water intake, exercise, and avoidance of prolonged sitting (Turner et al, 2006). It further appears that the support of a patient's partner can have a negative or positive impact on pain, disability, and sexual functioning (Smith et al, 2007b; Ginting et al, 2011).

Lifestyle Modification and Other Conservative Therapies

Conservative therapy should always be considered the primary therapy for CP/CPPS, despite the lack of evidence. Expert opinion and experience attest to the fact that conservative nonmedical and/or invasive therapies may provide the most benefit (Turner et al, 2006; Herati and Moldwin, 2013). My experience suggests that education (sometimes the only therapy required); avoidance of food, drink, and/or activities that exacerbate the symptoms; low-impact exercise (walking, elliptical machine, swimming, yoga, stretching); local heat therapy (hot water bottle, heating pad, hot tub or bath); and positive attitude and development of personal coping skills provide the basis on which all the other therapies rest. Most of these interventions, even diet modification (Herati et al, 2013), have not been proven in randomized clinical trials in CP/CPPS specifically; however, they have proven their worth in clinical practice (Turner et al, 2006) and in use with other pain syndromes (Giubilei et al, 2007).

Minimally Invasive Therapies

Balloon Dilatation. Lapatin and coworkers (1990) employed balloon dilatation in an uncontrolled trial of seven patients with nonbacterial prostatitis and prostatodynia and showed improvement in voiding symptoms during a 1- to 5-month follow-up. Pain and discomfort were not assessed. This treatment effect has never been substantiated, and balloon dilatation has not been routinely employed in clinical practice. Suzuki and coworkers (1995) combined the potential beneficial effects of balloon dilatation with prostatic hyperthermia in five men with CP/CPPS and demonstrated significant improvement in symptoms in one patient and partial improvement in three. Nickel and associates (1998b) were not able to duplicate this beneficial effect in a small pilot trial evaluating the "hot balloon" (heating by radiofrequency energy rather than laser energy).

Transurethral Needle Ablation. Chiang and associates (1997) employed transurethral needle ablation (TUNA) of the prostate in seven patients with chronic nonbacterial prostatitis, assessed the patients before and after therapy (6 months of follow-up) with a modification of the Symptom Severity Index (Nickel and Sorensen, 1996), and reported favorable results in four. A follow-up study by Chiang and Chiang (2004) showed significant improvement in symptoms in the majority of 32 patients treated with TUNA. However, Leskinen and colleagues (2002) investigated the effectiveness and durability of TUNA in 25 patients randomized to TUNA and eight patients randomized to sham treatment, and they reported that the efficacy of TUNA in CP/CPPS is comparable to that of sham treatment and so could not recommend TUNA as therapy for CP/CPPS.

Extracorporeal Shockwave Therapy. Extracorporeal shockwave lithotripsy has been suggested for the symptomatic relief of local perineal symptoms associated with CP/CPPS (Zimmerman et al, 2008). Zimmerman and colleagues (2009) randomized 60 men to perineal extracorporeal shockwave therapy (ESWT) or placebo and

showed statistically significant beneficial effects in comparison with placebo. Another study randomized 40 patients to ESWT or placebo (Vahdatpour et al, 2013), and this study again showed significant improvement in the treated group. This modality of therapy certainly should be further considered for a larger confirmatory clinical trial, especially because there seem to be few complications.

Minimally Invasive Neuromodulation Therapies. Neuromodulation techniques used for chronic pelvic pain conditions include sacral nerve stimulation (SNS), percutaneous tibial nerve stimulation (PTNS), and pudendal nerve stimulation (Yang, 2013). Ruedi and associates (2003) suggested that high-frequency electrostimulation may be harnessed to treat CP. Others (Schneider et al, 2013) have evaluated electrostimulation therapies and suggest that they might be beneficial. In a study published in the non-English literature, Yang and colleagues (2011) randomly divided a total of 140 patients with diagnosed CP/CPPS into a control group (n = 20), a biofeedback group (n = 40), an electrical stimulation group (n = 40), and a biofeedback plus electrical stimulation group (n = 40). Each treatment appeared to be better than the control group, with combination therapy being the most effective. In a study to evaluate posterior tibial nerve stimulation (Kabay et al, 2009), a total of 89 patients with therapy-resistant pelvic pain were randomized to receive either nerve stimulation (n = 45) or sham treatment (n = 44). The authors demonstrated that percutaneous PTNS may relieve pain in patients with category IIIB CP/CPPS. SNS has been studied in interstitial cystitis (bladder pain syndrome) (Yang, 2013), but the typical pain and lack of voiding symptoms in male CPPS make it much more difficult to treat and assess using this strategy (Yang et al, 2003). Yang (2013) reviewed the invasive neuromodulation literature and concluded that these modalities of therapy may eventually be proven to provide benefits for patients with CPPS. However, because of the paucity of data and the limitations of small studies, the conclusions of the existing literature must be carefully considered.

Microwave Hyperthermia and Thermotherapy. It is believed that the heat applied to the prostate gland by the microwave process could shorten the natural resolution of the inflammatory process, perhaps by accelerating the process of fibrosis or scar formation in the area of chronic inflammation. In addition, heat therapy, particularly with the higher temperatures achieved with transurethral microwave thermotherapy, could alter the afferent nerve fibers that convey the objective symptom of pain from the inflamed prostate gland (intraprostatic sympathectomy) (Perachino et al, 1993). It may even be possible that the microwave energy kills nonculturable or cryptic bacteria within the prostate gland (Sahin et al, 1998).

Although many uncontrolled trials employing heat therapy have shown benefit (Nickel, 1999b; Zeitlin, 2002), only three published studies have used sham controls, and unfortunately the NIH-CPSI was not available as an outcome parameter for these studies. Vassily and associates (1999) noted symptom improvement in 75% of men in a transrectal microwave hyperthermia-treated group compared with 52% of men in the sham-treated group. Shaw and colleagues (1993) documented treatment success (defined as a greater than 50% improvement in symptoms) in 55% of the men in a transrectal microwave hyperthermia group (15 patients) compared with 10% of patients treated with sham therapy (13 patients) at 3 months. Nickel and Sorensen (1996) examined the safety and efficacy of transurethral microwave thermotherapy in 20 men randomized to therapy or sham. At 3 months' follow-up, the transurethral microwave thermotherapy-treated patients had significantly improved symptom scores compared with sham-treated patients (7 of 10 men treated with transurethral microwave thermotherapy had a favorable result compared with 1 of 10 men treated with a sham therapy). A recently reported study in men with CP/CPPS treated with cooled transurethral microwave thermotherapy using the NIH-CPSI as an outcome (Kastner et al, 2004) again suggested that thermotherapy remains a promising treatment for intractable CP, particularly when it is associated with concomitant BPH. Although this prospective study showed a significant reduction in NIH-CPSI score compared with baseline in 35 men followed for 12 months, it was not a randomized sham controlled trial. Heat therapy appears to be a

promising therapeutic approach but, until larger-scale studies have been performed, should be restricted to patients with refractory or end-stage symptoms. In 2012, Gao and colleagues attempted to relate improvement they observed with transrectal hyperthermia with physiologic changes in the prostate.

Other Minimally Invasive Surgical Procedures. Serel and colleagues (1997) reported significantly meaningful beneficial effects of use of the neodymium:yttrium-aluminum-garnet laser in 30 patients with chronic abacterial prostatitis and prostatodynia. A number of other minimally invasive treatments have been examined in small pilot studies. These include pelvic and sacral electromagnetic therapy (Leippold et al, 2005; Rowe et al, 2005; Kim et al, 2013). It has been suggested that injection of botulinum toxin directly into the prostate may benefit some patients (Chuang and Chancellor, 2006). Botulinum toxin A (BTX-A) injection was evaluated in a small pilot study in which 29 patients were randomized to receive either BTX-A 100 U or normal saline injected into the perineal body and bulbospongiosus muscle (Gottsch et al, 2011). Total CPSI score did not reach significance in the BTX-A-treated group compared with controls; however, the CPSI pain subdomain score reached statistical significance in the BTX-A patients compared with controls ($P = .05$), with 30% of treated patients compared with 13% of placebo patients achieving at least minimal responder status ($P = .0002$).

Some minimally invasive surgical procedures (electrical neuromodulation, extracorporeal shock wave therapy, electroacupuncture, and perhaps transurethral microwave thermotherapy (TUMT) and botulinum toxin injection may be beneficial for treatment for CP/CPPS in selected patients (see Table 13-3); however, large, well-designed sham-controlled trials are required before these therapies can be considered recommended.

Traditional Surgery

In acute bacterial prostatitis (category I), urinary obstruction is a very common symptom. Traditionally it has been suggested that the insertion of a suprapubic cystostomy tube is the optimal therapy because an indwelling Foley catheter may further obstruct urethral ducts, resulting in the potential for development of prostate abscesses (Dajani and O'Flynn, 1968; Pai and Baht, 1972; Weinberger et al, 1988). In most patients, however, an in-and-out catheterization to relieve the initial obstruction or short-term (12 hours) indwelling catheterization with a small-caliber Foley catheter is appropriate. A developing prostate abscess, best detected with transrectal ultrasonography or computed tomography (Rovik and Doeblin, 1989), that fails to respond quickly to antibiotics is optimally drained by the transurethral incision route (Pai and Baht, 1972). However, transperineal incision and drainage (Granados et al, 1992) must be considered when the abscess has penetrated beyond the prostatic capsule or penetrated through the levator ani muscle. More recently it has been suggested that percutaneous drainage of the abscess is the most effective and less morbid procedure (Varkarakis et al, 2004).

Surgery does not have an important role in the treatment of most CP syndromes unless a specific indication is discovered during the evaluation of the patient (Kirby, 1999). These indications are usually noted during specific and ancillary investigations such as cystoscopy, transrectal ultrasonography, urodynamics, computed tomography, or MRI. Certainly, patients with urethral strictures benefit from surgical correction. Kaplan and associates (1994) have suggested that men with chronic nonbacterial prostatitis-like symptoms and urodynamic evidence of vesical neck obstruction benefit from endoscopic incision of the bladder neck.

Seminal vesicle abscesses can be managed with antibiotic therapy, transrectal aspiration, and, if necessary, an operation to remove the seminal vesicles. Traditionally, seminal vesiculectomy was performed as a difficult open procedure, but laparoscopic excision of the seminal vesicles was reported to be the least morbid procedure (Nadler and Rubenstein, 2001).

Radical transurethral resection of the prostate (Barnes et al, 1982; Sant et al, 1984) has been advocated in patients who have

either relapsing or refractory chronic bacterial prostatitis (category II) secondary to bacterial persistence within the prostate gland. Although prostatic calculi are not pathognomonic of prostatitis (Harada et al, 1980), it has been clearly shown that bacteria can persist in protective biofilms or aggregates within the interstices or on the surface of the calculus material (Meares, 1974; Nickel et al, 1994). Theoretically, removal of all the infected material, including potentially infected calculi, can be achieved (with appropriate intra-operative radiographs or ultrasound studies), but except for small anecdotal case series (Barnes et al, 1982; Sant et al, 1984) there is no substantial proof in the literature as to the efficacy of major prostate surgery in category II CP. Radical transurethral resection of the prostate has not been advocated for category III CP/CPPS, but open radical prostatectomy has been shown anecdotally to benefit a few patients with symptoms of nonbacterial prostatitis or prostatodynia or both (Davis and Weigel, 1990; Frazier et al, 1992). No definitive clinical series or long-term follow-up has ever been presented, and this type of surgery should not be encouraged or recommended at this time.

Phenotype Directed Multimodal Treatment Strategy

There are a number of reasons why the majority of randomized placebo- or sham-controlled trials reported in the literature and this chapter have been "negative" or only modestly "positive," making it difficult to develop evidence-based management guidelines. The first reason is that treatments based on a single causative mechanism may be doomed to fail when tested in the whole CP/CPPS population. As discussed earlier in the section on *etiology*, most of the mechanisms examined are based on sound scientific theory, and all are associated with at least some confirmatory clinical data. But it appears that patients have differing mechanisms and pathogenic progressions. We must accept that there is no one all-encompassing causative mechanism responsible for all cases of CP/CPPS. As further discussed in the section on *evaluation*, it is now evident that patients also have quite heterogeneous clinical phenotypes. In addition, one cannot be sure that the patients routinely managed in clinical practice are the same patients who have been enrolled in clinical trials. In fact, the most rigorously designed NIH-sponsored randomized controlled trials (Alexander et al, 2004; Nickel et al, 2008b; Pontari et al, 2010) did not enroll over 90% of the CP/CPPS patients who were screened. Finally, were the negative trials reported in the literature and this chapter really negative? A reappraisal of the study results would suggest otherwise. Antibiotics tended to work better in less chronic heavily pretreated patients (marginally significant improvement in levofloxacin trial [Nickel et al, 2003b] compared with ciprofloxacin trial [Alexander et al, 2004]), further substantiated by the 75% improvement seen with use of ciprofloxacin or levofloxacin treatment in patients with very early presentation (within 4 to 8 weeks of symptoms associated with that particular episode) (Nickel and Xiang, 2008). Whereas large NIH-sponsored multicenter studies failed to confirm the benefits of α -adrenergic blockers in both chronic heavily pretreated (Alexander et al, 2004) and recently diagnosed α -adrenergic blocker-naïve (Nickel et al, 2008b) CP/CPPS patients, at least six other randomized controlled trials (Cheah et al, 2003b; Mehik et al, 2003; Nickel et al, 2004b; Tugcu et al, 2007; Chen et al, 2011; Nickel et al, 2011a) with less rigorous selection criteria did show significant efficacy with α -adrenergic blockers. Although the results of trials examining anti-inflammatory agents (Nickel et al, 2003b), pentosan polysulfate (Nickel et al, 2005a), finasteride (Nickel et al, 2004b), celecoxib (Zhao et al, 2009), tanezumab (Nickel et al, 2012), and the neuro-modulator pregabalin (Pontari et al, 2010) were considered only marginally positive or even negative based on the primary end point analysis, these trials showed efficacy for many of the validated outcomes (including responder analyses using the validated subjective global or global response assessment scale) of statistical or marginal significance. In fact, when examined using a network meta-analysis approach, Anothaisintawee and colleagues (2011) evaluated all randomized controlled data for medical therapies and concluded that there was a statistically significant improvement compared with

placebo for almost all of these therapies. However, the clinical significance of this benefit and the disconnect between symptom score improvement and responder data indicate that these treatments are not very effective when used indiscriminately in the entire CP/CPPS population. It is very likely that we will never discover a single overall cure for all patients diagnosed with this condition. This reevaluation of trial results, however, strongly suggests that some patients do, in fact, respond to these various therapies. Multimodal therapy using multiple concurrent treatment strategies appears to offer the best results (Shoskes et al, 2003; Shoskes and Katz, 2005), at least compared with a sequential monotherapy approach (Nickel et al, 2004a; Nickel, 2008b). However, a number of well-controlled prospective studies did not demonstrate increased efficacy of combining α -adrenergic blockers and antibiotics (Alexander et al, 2004) or α -adrenergic blockers and anti-inflammatory agents (Batstone et al, 2005). The explanation for this difficulty in treating CP may be that the patients become peripherally and centrally sensitized and that treatment targeted to the local initiators of the early process may not work as well when the condition becomes chronic and outside the pelvis (Yang et al, 2003; Pontari and Ruggieri, 2004; Pontari, 2007). We must be able to identify patients who may respond to specific therapies, and at this time the UPOINT clinical phenotyping system comprehensively described in the evaluation section may be the best approach.

It has been suggested that UPOINT will be a new clinical tool for urologists to use to direct individually based therapy.

Each domain has been clinically defined using standard clinical assessment and linked to specific mechanisms of symptom production or propagation (see evaluation section for details). Each of these domains has been associated with specific therapy based on best evidence and expert experience (Fig. 13-9). One clinical trial assessing this approach in CP/CPPS showed what appeared to be a superior clinical benefit. In this study by Shoskes and associates (2010) almost 100 consecutive men referred to a tertiary CP clinic were categorized according to the UPOINT system and then treated according to an algorithm similar to that described in this chapter (see Fig. 13-9) and followed for 6 months. A 6-point decrease in NIH-CPSI total score is believed to be a clinically significant achievement in these chronic heavily pre-treated patients, and 84% of men reported this level of improvement at 6 months. The overall NIH-CPSI mean score in the group decreased from 25.2 (± 6.1) to 13.2 (± 7.2) a clinically and statistically significant ($P < .0001$) result. Based on previous clinical trial data, poor clinical experience with providing treatment benefits to CP/CPPS patients, initial studies, and ongoing experience in the clinic, the European (Engeler et al, 2013), Canadian (Nickel, 2011), and International Consultation on Urinary Disease (Nickel et al, 2013b) guidelines suggest that a phenotypic approach to therapy as described by the UPOINT system be considered for clinical practice. (Criteria for inclusion in the specific CP/CPPS domains and suggested directed therapies are shown in Fig. 13-9.)

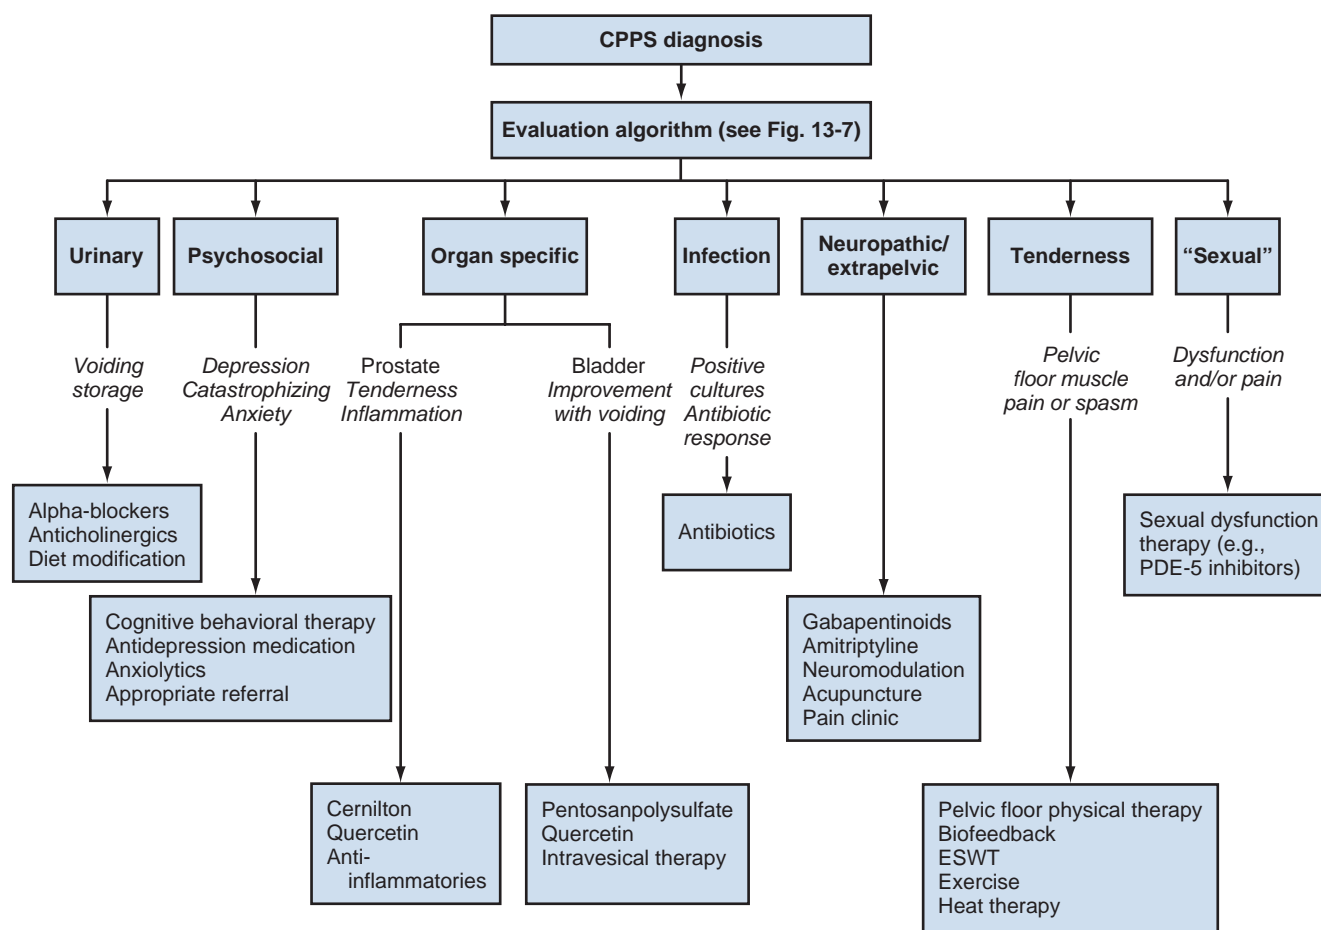

Figure 13-9. A suggested diagnostic and therapeutic algorithm for the treatment of patients with chronic prostatitis and chronic pelvic pain syndrome (CPPS) based on the UPOINT clinical phenotyping strategy. ESWT, extracorporeal shockwave therapy; PDE-5, phosphodiesterase type 5. (Modified from Nickel JC. Prostatitis. CUA Guideline. Can Urol Assoc J 2011;5:306–15; and Nickel JC, Wagenlehner F, Pontari M, et al. Male chronic pelvic pain syndrome (CPPS). In: Chapple C, Abrams P, editors. Male lower urinary tract symptoms (LUTS). An International Consultation on Male LUTS, Fukuoka, Japan, Sept 30-Oct 4, 2012. Montreal: Société Internationale d'Urologie (SIU); 2013. p. 331–72.)

Treatment Summary

Acute bacterial prostatitis is relatively simple to treat; the bacteria are eradicated with appropriate antibiotic therapy. However, ESBL infection related to prostate biopsy is becoming a worldwide problem. The objective for chronic bacterial prostatitis is similar—eradication of bacteria—but long-term symptom amelioration sometimes eludes us. Our standard therapies for CP/CPPS, when used as monotherapy, offer only modest improvement in symptoms (Nickel et al, 2004a, 2008b). Box 13-2 outlines a list of the various standard therapies that are currently recommended. Table 13-4 describes the standard doses of the various medical therapies.

To evaluate and compare the many clinical trials assessing the various therapies advocated for CP/CPPS it is important to clearly define and classify the patient population (NIH classification system), determine results by using a standardized outcome index (NIH-CPSI), prospectively compare a treated group with a similar group randomized to placebo, and fulfill the requirements of peer review for publication in a reputable

BOX 13-2 Suggested Therapies for Chronic Prostatitis and Chronic Pelvic Pain Syndrome (National Institutes of Health Category III)

RECOMMENDED

1. α -Blocker therapy as part of a multimodal treatment strategy for newly diagnosed, α blocker-naïve patients who have voiding symptoms.
2. Antimicrobial therapy trial for selected newly diagnosed, antimicrobial-naïve patients.
3. Selected phytotherapies: Cernilton and Quercetin.
4. Multimodal therapy directed by clinical phenotype.
5. Directed physiotherapy. Although level 1 evidence is not available, evidence from multiple weak trials and vast clinical experience strongly suggests benefit for selected patients.

NOT RECOMMENDED

1. α -Blocker monotherapy, particularly in patients previously treated with α -blockers.
2. Anti-inflammatory monotherapy.
3. Antimicrobial therapy as primary therapy, particularly for patients in whom treatment with antibiotics has previously failed.
4. 5 α -Reductase inhibitor monotherapy; can be considered in older patients with coexisting benign prostatic hyperplasia.
5. Most minimally invasive therapies such as transurethral needle ablation (TUNA), laser therapies.
6. Invasive surgical therapies such as transurethral resection of the prostate (TURP) and radical prostatectomy.

REQUIRING FURTHER EVALUATION

1. Low-intensity shock wave treatment.
2. Acupuncture.
3. Biofeedback.
4. Invasive neuromodulation (e.g., pudendal nerve modulation).
5. Electromagnetic stimulation.
6. Botulinum toxin A injection.
7. Medical therapies including meparticin, muscle relaxants, neuromodulators, immunomodulators.

Modified from Nickel JC, Wagenlehner F, Pontari M, et al. Male chronic pelvic pain syndrome (CPPS). In: Chapple C, Abrams P, editors. Male lower urinary tract symptoms (LUTS). An International Consultation on Male LUTS, Fukuoka, Japan, Sept 30-Oct 4, 2012. Montreal: Société Internationale d'Urologie; 2013. p. 331–72.

journal (Nickel et al, 1999b; Probert et al, 2002). In the past several years the results of a significant number of such trials have been published (Nickel, 2004; Schaeffer, 2006; Nickel, 2008a; Anothaisintawe et al, 2011; Nickel, 2011; Cohen et al, 2012; Thakkestian et al, 2012; Engeler et al, 2013; Nickel et al, 2013a), allowing the reader to assess and compare the efficacy of antibiotics, α -adrenergic blockers, anti-inflammatory agents, phytotherapies, hormonal agents, and minimally invasive approaches in CP/CPPS (see Tables 13-2 and 13-3). A patient-directed phenotypic strategy (such as the UPOINT approach), developing a unique best-evidence multimodal treatment plan for each individual, may be the optimal way to use the available clinical trial data to ultimately improve patient management in CP/CPPS (see Fig. 13-9).

KEY POINTS: THERAPY

- The following medical therapies have been evaluated in standardized randomized placebo-controlled trials in chronic pelvic pain syndrome (CPPS): antibiotics, α -adrenergic blockers, anti-inflammatory agents, hormonal therapies, phytotherapies, and pregabalin. The following minimally invasive therapies have been evaluated in randomized placebo- or sham-controlled trials in CPPS: extracorporeal shockwave therapy (ESWT), transurethral microwave therapy (TUMT), and neuromodulation (electrostimulation, botulinum toxin).
- The following therapies have shown benefits in placebo- or sham-controlled studies in CPPS: marked benefit—none; moderate benefit in some selected trials— α -adrenergic blockers and pregabalin; and modest benefit—anti-inflammatory agents, phytotherapies, ESWT, TUMT, selected neurostimulation.
- Specific multimodal therapy directed at individual UPOINT phenotypes may result in better management outcomes.

OTHER INFLAMMATORY AND PAIN CONDITIONS OF THE LOWER URINARY TRACT

Orchitis

Definition and Classification

By definition, orchitis is inflammation of the testis, but the term has been used to describe testicular pain localized to the testis without objective evidence of inflammation. Acute orchitis represents sudden occurrence of pain and swelling of the testis associated with acute inflammation of that testis. Chronic orchitis involves inflammation and pain in the testis, usually without swelling, persisting for more than 6 weeks. A classification (Nickel and Beiko, 2001) based on cause is presented in Box 13-3.

Pathogenesis and Etiology

Isolated orchitis is a relatively rare condition and is usually viral in origin. It spreads to the testis by a hematogenous route. Most cases of orchitis, particularly bacterial, occur secondary to local spread of an ipsilateral epididymitis and are referred to as *epididymo-orchitis*. UTIs are usually the underlying source in boys and elderly men. In young sexually active men, sexually transmitted diseases are often responsible (Berger, 1998). Truly noninfectious orchitis is often idiopathic or related to trauma, although autoimmune disease has rarely been implicated (Pannek and Haupt, 1997). It may be impossible to clinically distinguish chronic orchitis from chronic orchialgia.

Bacterial orchitis is usually associated with epididymitis and is therefore often caused by urinary pathogens, including *E. coli* and *Pseudomonas*. Less commonly, *Staphylococcus* species or *Streptococcus* species are responsible. The most common sexually transmitted

TABLE 13-4 Suggested Medical Therapy for Chronic Prostatitis and Chronic Pelvic Pain Syndrome

DRUG CLASS	SPECIFIC THERAPY	DOSE	DURATION OF THERAPY (WK)	EVIDENCE
Antibiotics	TMP-SMX	160/800 mg bid	12	See text for summary of clinical trial data.
	Norfloxacin	400 mg bid	4-12	
	Ciprofloxacin	500 mg bid	4-12	
	Ofloxacin	300 mg bid	4-12	
	Lomefloxacin	400 mg qd	4-12	
	Levofloxacin	500 mg qd	4-12	
α -Adrenergic blockers	Terazosin	5 mg qd	>14	Cheah et al, 2003b Mehik et al, 2003 Nickel et al, 2008b Nickel et al, 2004c Alexander et al, 2004 Nickel et al, 2011a
	Alfuzosin	10 mg qd	>12

BOX 13-3 Classification of Orchitis

- Acute bacterial orchitis
 - Secondary to urinary tract infection
 - Secondary to sexually transmitted disease
- Nonbacterial infectious orchitis
 - Viral
 - Fungal
 - Parasitic
 - Rickettsial
- Noninfectious orchitis
 - Idiopathic
 - Traumatic
 - Autoimmune
- Chronic orchitis
- Chronic orchialgia

microorganisms responsible are *Neisseria gonorrhoeae*, *C. trachomatis*, and *Treponema pallidum*. Xanthogranulomatous orchitis, usually associated with *Proteus* and *E. coli*, is an extremely rare inflammatory destructive lesion of the testes that is treated with orchiectomy (Al-Said et al, 2007; Kang et al, 2007).

Mycobacterial infections, tuberculosis (Chen et al, 2004; Park et al, 2008; Gomez-Garcia et al, 2010), and BCG therapy (Hill et al,

2008) can also cause orchitis. The most common cause of **viral orchitis** is mumps (Jalal et al, 2004; Masarani et al, 2006; Emerson et al, 2007; Davis et al, 2010), but infectious mononucleosis has also been implicated (Weiner, 1997). **Fungal infections** occasionally involve the testis, with candidiasis, aspergillosis, histoplasmosis, coccidioidomycosis, blastomycosis, and actinomycosis all having been reported as causes of orchitis (Wise, 1998). **Parasitic infections** rarely cause orchitis in the Western Hemisphere, but filariasis (Hazen Smith and von Lichtenberg, 1998) and trypanosomiasis (Ehrhardt et al, 2006) have been described in some endemic areas of Africa, Asia, and South America.

Autoimmune orchitis can be a relevant cause of decreased fecundity in males with the concomitant presence of anti-sperm antibodies. Causes of this variant of orchitis and/or testicular vasculitis are associated with autoimmune diseases, mainly those with primary vasculitis such as polyarteritis nodosa, Behçet disease, and Henoch-Schönlein purpura (Hedger, 2011; Silva et al, 2012).

Diagnosis

In patients with **acute infectious orchitis**, history discloses a recent onset of testicular pain, often associated with abdominal discomfort, nausea, and vomiting. These symptoms may be preceded by symptoms of parotitis in boys or young men, by UTIs in boys or elderly men, or alternatively by symptoms of a sexually transmitted disease in sexually active men. Although the process is usually unilateral, it is sometimes bilateral, especially if viral. Physical examination may reveal a toxic and febrile patient. The skin of the

involved hemiscrotum is erythematous and edematous, and the testis is quite tender to palpation or can be associated with a transilluminating hydrocele. The patient should be clinically assessed for prostatitis and urethritis. For acute noninfectious orchitis the clinical picture resembles the just-presented description except that these patients lack the toxic appearance and fever.

For **chronic orchitis and orchialgia** there may have been a history of previous episodes of testicular pain, usually secondary to acute bacterial orchitis, trauma, or other causes. The patient has chronic testicular (and possibly epididymal) pain to a degree that could seriously affect his day-to-day functioning and quality of life. Patients with this diagnosis usually become very frustrated with this problem. On examination the patient does not appear toxic and does not have a fever. The scrotum is not usually erythematous, but the testis may be somewhat indurated and is almost always tender to palpation.

Laboratory tests employed to assist in the diagnosis include urinalysis, urine microscopy, and urine culture. For a patient in whom a sexually transmitted disease is suspected, a urethral swab should also be taken for culture. If the diagnosis is not evident from the history, physical examination, and these simple tests, scrotal ultrasonography should be performed (to rule out malignancy in patients with chronic orchitis or orchialgia). Color Doppler ultrasonography is a reasonably reliable method for evaluating patients with scrotal diseases, including swelling and pain (Rizvi et al, 2011), and MRI has been suggested as a second-line investigation (Parenti et al, 2009; Makela et al, 2011). The most important differential diagnosis in young men and boys is testicular torsion. Testicular torsion is often difficult to differentiate from an acute inflammatory condition. Scrotal ultrasound evaluations (with use of Doppler imaging to determine testicular blood flow) are especially helpful in differential diagnosis (Mernagh et al, 2004; Gunther et al, 2006), but occasionally the diagnosis will be missed (particularly with intermittent or partial torsion) and the clinician should err in favor of the surgically correctable diagnosis of torsion.

Treatment

General principles of therapy include bed rest, scrotal support, hydration, antipyretics, anti-inflammatory agents, and analgesics. **Antibiotic therapy** (specific for UTIs, prostatitis, or sexually transmitted diseases) should be employed for infectious orchitis and is ideally based on culture and sensitivity testing but may be based on microscopic or Gram stain results. Orchitis resulting from *Mycobacterium tuberculosis* infection requires treatment with antituberculous drugs (rifampin, isoniazid, and pyrazinamide or ethambutol) and rarely surgery (Gomez-Garcia et al, 2010). There are no specific antiviral agents available to treat orchitis caused by mumps, and the previously mentioned supportive measures are important. If early testing findings are negative or results are unavailable, empirical treatment should be initiated, directed at the most likely pathogens based on the available clinical information; a fluoroquinolone would be the best agent in this scenario. Most patients can be readily managed on an outpatient basis. Surgical intervention is rarely indicated, unless testicular torsion (or rarely xanthogranulomatous orchitis) is suspected (as discussed previously). Spermatic cord blocks with injection of a local anesthetic may sometimes be needed to relieve severe pain. Abscess formation is rare; if it does occur, then percutaneous or open drainage is necessary. Glucocorticoids and immunosuppressive drugs may be indicated in autoimmune orchitis-associated active systemic autoimmune diseases (Silva et al, 2012).

Treatment of chronic orchitis or orchialgia is supportive. Anti-inflammatory agents, analgesics, support, heat therapies, and nerve blocks all have a role in ameliorating symptoms. Neuromodulation, usually medical (tricyclic antidepressants or gabapentinoids), can be helpful, and SNS has been suggested as a potential treatment modality (McJunkin et al, 2009), but the evidence is not really available to justify this invasive procedure at this time. It is generally believed that the condition is self-limited but could take years (and sometimes decades) to resolve. **Orchidectomy is indicated only in**

cases in which pain control is refractory to all other measures (and even this might not be successful in alleviating the chronic pain) (Nariculam et al, 2007).

Epididymitis

Definitions and Classification

Epididymitis by definition is inflammation of the epididymis. **Acute epididymitis** represents sudden occurrence of pain and swelling of the epididymis associated with acute inflammation of the epididymis (Nickel et al, 2002). **Chronic epididymitis** refers to inflammation and pain in the epididymis, usually without swelling (but with induration in long-standing cases), persisting for over 6 weeks (Nickel et al, 2002). Inflammation is not always clinically evident in many cases of localized epididymal pain. Approximately 1 man in 100 attending a North American urology clinic has a diagnosis of epididymitis (Nickel et al, 2005b). In the late 1990s the average cost per episode of epididymitis managed in the United States was \$368 (Gift and Owens, 2006), a cost considerably less than that reported for men with a diagnosis of CP. A classification for epididymitis is presented in Box 13-4 (Nickel et al, 2002).

Pathogenesis and Etiology

Acute epididymitis usually results from the spread of infection from the bladder, urethra, or prostate via the ejaculatory ducts and vas deferens into the epididymis. The process starts in the tail of the epididymis and then spreads through the body of the structure to the head of the epididymis. In infants and boys, epididymitis is often related to a UTI and/or an underlying genitourinary congenital anomaly (Merlini et al, 1998) or even to the presence of a foreskin (Bennett et al, 1998). In elderly men, BPH and associated stasis, UTI, and catheterization are the most common causes of epididymitis. Bacterial prostatitis and/or seminal vesiculitis are associated with epididymal infection in postpubertal males of all ages (Furuya et al, 2004). In sexually active men younger than 35 years of age, epididymitis is commonly the result of a sexually transmitted infection (Berger, 1998). In most cases of acute epididymitis, the testis is also involved in the process and thus the condition is referred to as *epididymo-orchitis*.

Chronic epididymitis may result from inadequately treated acute epididymitis, recurrent epididymitis, or some other cause including associations with other disease processes such as Behçet disease (Cho et al, 2003; Arromdee and Tanakitviriul, 2006; Pektas et al, 2008) or treatment with amiodarone (Nikolaou et al, 2007). The cause of chronic epididymalgia is usually unclear. Certainly one of the best known and studied is the chronic epididymitis

BOX 13-4 Classification of Epididymitis

- Acute bacterial epididymitis
 - Secondary to urinary tract infection
 - Secondary to sexually transmitted disease
- Nonbacterial infectious epididymitis
 - Viral
 - Fungal
 - Parasitic
- Noninfectious epididymitis
 - Idiopathic
 - Traumatic
 - Autoimmune
 - Amiodarone-induced
 - Associated with a known syndrome (e.g., Behçet disease)
- Chronic epididymitis
- Chronic epididymalgia

or epididymalgia that occurs in some men after a vasectomy. About 1 in 100 men describe severe pain 6 months after a vasectomy that noticeably affects their quality of life (up to 15% of men report some discomfort 6 months after the procedure) (Leslie et al, 2007).

The most common causative microorganisms in the pediatric and elderly age groups are the coliform organisms that cause bacteriuria (Berger et al, 1979). In men younger than age 35 who are sexually active with women, the most common offending organisms causing epididymitis are the usual bacteria that cause urethritis, namely *N. gonorrhoeae* and *C. trachomatis* (Ito et al, 2012). In homosexual men who practice anal intercourse, *E. coli* and *Haemophilus influenzae* are most commonly responsible. Both tuberculosis (Liu et al, 2005; Tsili et al, 2008) and mycobacteria, such as BCG (Harada et al, 2006), can be associated with epididymitis. As with orchitis, viral, fungal, mycoplasmal, and parasitic microorganisms have all been implicated in epididymitis (Berger, 1998; Hazen Smith and von Lichtenberg, 1998; Wise, 1998; Scagni et al, 2008). Rarely, epididymitis as a complication of brucellosis has been described (Akinci et al, 2006; Queipo-Ortuno et al, 2006; Colmenero et al, 2007).

Diagnosis

Both acute infectious and acute noninfectious epididymitis manifest in much the same way as do acute infectious and acute noninfectious orchitis, respectively. Physical examination localizes the tenderness to the epididymis. However, in many cases the testis is also involved in the inflammatory process and subsequent pain; this is referred to as *epididymo-orchitis*. The spermatic cord is usually tender and swollen. Early in the process only the tail of the epididymis is tender, but the inflammation quickly spreads to the rest of the epididymis, and if it continues to the testis then the swollen epididymis becomes indistinguishable from the testis.

There may be no clinical or etiologic differentiation between chronic epididymitis and epididymalgia. The patient usually has a long-standing history of pain (waxing and waning or constant) localized to the epididymis, and, as with chronic orchitis and orchialgia, these symptoms may have a significant impact on the patient's quality of life (Nickel et al, 2002).

Laboratory tests should include Gram staining of a urethral smear and a midstream urine specimen. Gram-negative bacilli can usually be identified in patients with underlying cystitis. If the urethral smear reveals the presence of intracellular gram-negative diplococci, a diagnosis of infection with *N. gonorrhoeae* is established. If only WBCs are seen on the urethral smear, a diagnosis of *C. trachomatis* will be established two thirds of the time. A urethral swab and midstream urine specimen should be sent for culture and sensitivity testing. When an infant or young boy is diagnosed with epididymitis, he should be further evaluated with abdominopelvic ultrasonography, voiding cystourethrography, and possibly cystoscopy (Shortliffe and Dairiki, 1998; Al-Taheini et al, 2008). If the diagnosis is uncertain, duplex Doppler scrotal ultrasonography to look for increased blood flow to the affected epididymis may be performed (also to rule out torsion as described in the section on orchitis) (Mernagh et al, 2004; Rizvi et al, 2011). Ultrasonography can sometimes be helpful to rule out other epididymal and scrotal pathology (Lee et al, 2008). MRI can be considered a second-line investigation (Parenti et al, 2009; Makela et al, 2011).

Treatment

Management of acute infectious epididymitis depends on the likely cause and organism (Tracy et al, 2008). The Centers for Disease Control and Prevention's 2006 guidelines for the treatment of infectious epididymitis included ceftriaxone or doxycycline for men younger than age 35 years and levofloxacin or ofloxacin for men older than age 35 years (Centers for Disease Control and Prevention et al, 2006). The guidelines updated in 2010 (Centers for Disease Control and Prevention, 2010) have not changed the ceftriaxone recommendation but suggest that azithromycin could

be used instead of doxycycline. The recent U.K. guidelines (Street et al, 2011) are very similar.

For chronic epididymitis, a 4- to 6-week trial of antibiotics that would potentially be effective against possible bacterial pathogens and particularly *C. trachomatis* may be appropriate (Nickel, 2005). Anti-inflammatory agents, analgesics, scrotal support, and nerve blocks have all been recommended as empirical treatment (Nickel, 2005). It is generally believed that chronic epididymitis is a self-limited condition that will eventually "burn out," but this could take years (or even decades). Surgical removal of the epididymis (epididymectomy) should be considered only when all conservative measures have been exhausted and the patient accepts that the operation will have at best a 50% chance of curing his pain (Padmore et al, 1996; Tracy et al, 2008; Callear and Masood, 2009). Successful spermatic cord block (temporary pain relief) does seem to predict a better result with surgery (Benson et al, 2013). Better surgical results (up to 70%) have also been reported for epididymectomy for postvasectomy pain (Siu et al, 2007; Lee et al, 2011). It has recently been reported that inhibition of adhesion and fibrosis after epididymectomy with local application of hyaluronic acid and carboxymethylcellulose improves pain relief and patient satisfaction (Chung et al, 2013). Many clinicians have shown that microsurgical denervation of the spermatic cord may achieve the same results as a complete epididymectomy (Choa et al, 1992; Heidenreich et al, 2002; Strom and Levine, 2008; Parekattil et al, 2013).

KEY POINTS: ORCHITIS AND EPIDIDYMITIS

- Orchitis usually occurs with epididymitis (except for viral causation).
- The cause of epididymitis and orchitis is usually related to the age of the patient.
- Acute presentation is usually related to infection or ischemia.
- In the young patient the most important differential diagnosis is torsion of the testis.
- Treatment of chronic epididymitis or epididymo-orchitis is difficult.

Diagnosis

Classification

Treatment

Principles of Management

Bladder pain syndrome or interstitial cystitis (BPS/IC) is a **condition diagnosed on a clinical basis** and requiring a high index of suspicion on the part of the clinician. It is a deceptively intricate disorder that should be considered in the differential diagnosis of the patient with chronic pelvic pain, pressure, or discomfort often exacerbated by bladder filling, and associated with at least one other urinary symptom, often urinary frequency. One can argue that it is a *symptom complex* because it has a differential diagnosis that should be explored in a timely fashion before or at the time of initiation of empirical therapy (Blaiwas, 2007). It is a diagnosis of exclusion in a patient who has experienced the symptoms for at least 6 weeks. Once other conditions have been ruled out, it can be considered a syndrome that typically responds to one of a variety of therapeutic approaches in the majority of cases. Symptoms compatible with the diagnosis are now thought to affect up to 3% of the female population (Berry et al, 2011). Although the female-to-male ratio has historically been about 5 : 1, newer epidemiologic data suggest that male symptom prevalence may approach that of female symptom prevalence in the United States (Suskind et al, 2013a).

The perception that the original term, *interstitial cystitis*, was not at all descriptive of the clinical syndrome, or even the pathologic findings in many patients, led to the current effort to reconsider the name of the disorder and even the way it is positioned in the medical spectrum (Hanno, 2008a). What was originally considered a bladder disease is now considered a chronic pain syndrome (Janicki, 2003) that may begin as a pathologic process in the bladder in most but not all patients and eventually can develop into a condition that, in a small subset of those affected, even cystectomy may not benefit (Baskin and Tanagho, 1992). Its relationship to type 3 chronic pelvic pain syndrome (CPPS) or nonbacterial prostatitis is unclear (Chai, 2002; Hakenberg and Wirth, 2002). Its association with other chronic pain syndromes has taken on more importance recently as a promising clue in unlocking the challenging etiologic and therapeutic puzzle of this condition (Rodríguez et al, 2009).

BPS/IC encompasses a major portion of the “painful bladder” disease complex. Painful bladder disorders involve a large group of patients with bladder, urethral, and/or pelvic pain; irritative voiding symptoms (urgency, frequency, nocturia, dysuria); and sterile urine cultures. Painful bladder conditions with well-established causes include radiation cystitis, cystitis caused by microorganisms that are not detected by routine culture methodologies, ketamine cystitis (Winstock et al, 2012), and systemic

disorders that affect the bladder. In addition, many gynecologic disorders can mimic BPS/IC (Kohli et al, 1997; Howard 2003a, 2003b). BPS/IC has no easily discernible cause.

The symptoms are allodynic, an exaggeration of normal sensations. There are no pathognomonic findings on pathologic examination, and even the finding of petechial hemorrhages on the bladder mucosa during cystoscopy after bladder hydrodistention under anesthesia is no longer considered the *sine qua non* of BPS/IC (Erickson, 1995; Waxman et al, 1998; Erickson et al, 2005). BPS/IC is truly a diagnosis of exclusion. It may have multiple causes and represent a final common reaction of the bladder to different types of insult. Misdiagnosis as a psychological problem, an overactive bladder, or chronic urinary infection has plagued patients with the syndrome. A distinct subgroup of patients with discrete inflammatory lesions in the bladder lining (Hunner lesions) involves specific characteristics, and successful treatment of this subgroup is available (Nordling et al, 2012).

DEFINITION

“It resembles a constellation of stars; its components are real enough but the pattern is in the eye of the beholder” (Mäkelä and Heliövaara, 1991). This evocative description of fibromyalgia could equally apply to BPS/IC. Indeed, it has been argued, not necessarily convincingly, that each medical specialty has at least one somatic syndrome (irritable bowel syndrome, chronic pelvic pain, fibromyalgia, tension headache, noncardiac chest pain, hyperventilation syndrome) that might be better conceptualized as a part of a general functional somatic syndrome than with the symptom-based classification that we have now, which may be more reflective of professional specialization and access to care (Wessely and White, 2004).

BPS/IC is a clinical diagnosis based primarily on chronic symptoms of pain perceived by the patient to emanate from the bladder and/or pelvis associated with urinary urgency or frequency in the absence of another identified cause for the symptoms. It has been defined and redefined over the last century, and as the problem of definition has become more prominent lately, so have the number of definitions and attempts to crystallize just what the diagnosis means (Box 14-1). The International Continence Society (ICS) prefers the term *painful bladder syndrome*, defined as “the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and night-time frequency, in the absence of proven urinary infection

BOX 14-1 History of Definitions of Bladder Pain Syndrome, Painful Bladder Syndrome, and Interstitial Cystitis Syndrome

- 1887, Skene (*Skene, 1887*): An inflammation that has destroyed the mucous membrane partly or wholly and extended to the muscular parietes.
- 1915, Hunner (*Hunner, 1915*): A peculiar form of bladder ulceration whose diagnosis depends ultimately on its resistance to all ordinary forms of treatment in patients with frequency and bladder symptoms (spasms).
- 1951, Bourque (*Bourque, 1951*): Patients who suffer chronically from their bladder—the ones who are distressed, not only periodically but constantly, having to urinate at all hours of the day and of the night and suffering pains every time they void.
- 1978, Messing and Stamey (*Messing and Stamey, 1978*): Non-specific and highly subjective symptoms of around-the-clock frequency, urgency, and pain somewhat relieved by voiding when associated with glomerulations on bladder distention under anesthesia.
- 1990, Revised National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) criteria (*Wein et al, 1990*): Pain associated with the bladder or urinary urgency, and glomerulations or Hunner ulcer on cystoscopy under anesthesia, in patients with symptoms for 9 months or longer—at least eight voids per day, one void per night, and cystometric bladder capacity less than 350 mL.
- 1997, NIDDK Interstitial Cystitis Data Base study entry criteria (*Simon et al, 1997*): Unexplained urgency or frequency (seven or more voids per day) or pelvic pain, of at least 6 months' duration in the absence of other definable causes.
- 2008, European Society for the Study of Interstitial Cystitis (ESSIC) (*van de Merwe et al, 2008*): Chronic (longer than 6 months) pelvic pain, pressure, or discomfort perceived to be related to the urinary bladder accompanied by at least one other urinary symptom such as persistent urge to void or frequency. Confusable diseases as the cause of the symptoms must be excluded.
- 2009, Japanese Urological Association (*Homma et al, 2009*): A disease of the urinary bladder diagnosed by three conditions: (1) lower urinary tract symptoms such as urinary frequency, bladder hypersensitivity, and/or bladder pain; (2) bladder pathology proven endoscopically by Hunner ulcer and/or mucosal bleeding after overdistention; and (3) exclusion of confusable diseases such as infection, malignancy, or calculi of the urinary tract.
- 2009, Society for Urodynamics and Female Urology (SUFU) informal international dialogue consensus meeting (*Hanno and Dmochowski, 2009*): An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of longer than 6 weeks' duration, in the absence of infection or other identifiable causes.
- 2011, American Urological Association: An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of longer than 6 weeks' duration, in the absence of infection or other identifiable causes.

or other obvious pathology" (*Abrams et al, 2002*). The ICS reserves the diagnosis of *interstitial cystitis* for patients with "typical cystoscopic and histological features," without further specifying these. This definition may miss 36% of patients, primarily because it confines the pain to a suprapubic location and mandates a relationship of pain to bladder filling (*Warren et al, 2006*).

In the absence of clear criteria for IC, this chapter will refer to BPS/IC and IC interchangeably, because all but recent literature terms the syndrome *interstitial cystitis*. The definition of the European Society for the Study of Interstitial Cystitis (ESSIC) is a clinically useful one, and changes made since its original iteration have likely made it more sensitive and inclusive (*Mouracade et al, 2008*). Minor modifications made at a meeting under the auspices of the Society for Urodynamics and Female Urology (SUFU) may be preferred by some clinicians. The SUFU definition was adopted in the guidelines of the American Urological Association (AUA) along with the nomenclature *interstitial cystitis/bladder pain syndrome* (*Hanno et al, 2011*). Perhaps more than for most diseases, how we arrived at this point is instructive and critical to an overall understanding of BPS/IC. The paradigm change that has resulted in morphing what was originally considered a bladder disease (aptly named *interstitial cystitis*) to a chronic pain syndrome (*bladder pain syndrome*) also merits discussion.

HISTORICAL PERSPECTIVE

Recent historical reviews confirm that IC was recognized as a pathologic entity during the 19th century (*Christmas and Sant, 1997; Parsons and Parsons, 2004*). Joseph Parrish, a Philadelphia surgeon, described three patients with severe lower urinary tract symptoms in the absence of a bladder stone in an 1836 text (*Parrish, 1836*), and termed the disorder *tic douloureux of the bladder*. Teichman argued that this may represent the first description of IC (*Teichman*

et al, 2000). Fifty years later Skene used the term *interstitial cystitis* to describe an inflammation that had "destroyed the mucous membrane partly or wholly and extended to the muscular parietes" (*Skene, 1887*).

Early in the 20th century, at a New England Section meeting of the AUA, Guy Hunner reported on eight women with a history of suprapubic pain, frequency, nocturia, and urgency lasting an average of 17 years (*Hunner, 1915, 1918*). He drew attention to the disease, and the red, bleeding areas he described on the bladder wall came to be called *Hunner ulcers*. As *Walsh (1978)* observed, this has proved to be unfortunate. In the early part of the 20th century, the very best cystoscopes available gave a poorly defined and ill-lit view of the fundus of the bladder. It is not surprising that when Hunner saw red and bleeding areas high on the bladder wall, he thought they were ulcers. For the next 60 years, urologists would look for ulcers and fail to make the diagnosis in their absence. The disease was thought to be focal, rather than a pancystitis.

Hand (1949) authored the first comprehensive review about the disease, reporting on 223 patients. In looking back, his paper was truly a seminal one, years ahead of its time. Many of his epidemiologic findings have held up to this day. His description of the clinical findings bears repeating. "I have frequently observed that what appeared to be a normal mucosa before and during the first bladder distention showed typical interstitial cystitis on subsequent distention." He noted "small, discrete, submucosal hemorrhages, showing variations in form ... dot-like bleeding points ... little or no restriction to bladder capacity." He portrayed three grades of disease, with grade 3 matching the small-capacity, scarred bladder described by Hunner. Sixty-nine percent of patients had grade 1 disease, and only 13% had grade 3.

Walsh (1978) later coined the term *glomerulations* to describe the petechial hemorrhages that Hand had described. But it was not until *Messing and Stamey (1978)* discussed the "early diagnosis" of IC that attention turned from looking for an ulcer to make the diagnosis to the concepts that (1) symptoms and glomerulations at

the time of bladder distention under anesthesia were the disease hallmarks, and (2) the diagnosis was primarily one of exclusion.

Bourque's "Aunt Minnie description" of IC (i.e., it is hard to define, but one knows it when one sees it) is more than 60 years old and is worth recalling. "We have all met, at one time or another, patients who suffer chronically from their bladder; and we mean the ones who are distressed, not only periodically but constantly, having to urinate often, at all moments of the day and of the night, and suffering pains every time they void. We all know how these miserable patients are unhappy, and how those distressing bladder symptoms get finally to influence their general state of health physically at first, and mentally after a while" (Bourque, 1951).

Although memorable, this description and others like it were not suitable for defining this disease in a manner that would help physicians make the diagnosis and design research studies to learn more about the problem. Physician interest and government participation in research were sparked through the efforts of a group of frustrated patients led by Dr. Vicki Ratner, an orthopedic surgery resident in New York City, who founded the first patient advocacy group, the Interstitial Cystitis Association, in the living room of her small New York City apartment in 1984 (Ratner et al, 1992, 1997). The first step was to develop a working definition of the disease. The modern history of BPS/IC is best viewed through the development of the modern definition.

Evolution of the Definition

There are data to suggest that true urinary frequency in women can be defined as regularly having to void at intervals of less than 3 hours, and that of women older than 40 years, 25% have nocturia at least once (Glennings, 1985; Fitzgerald and Brubaker, 2003). Whereas bladder capacity tends to fall in women by the eighth and ninth decades of life, bladder volume at first desire to void tends to rise as women age (Collas and Malone-Lee, 1996). Based on a 90th percentile cutoff to determine the ranges of normality, the highest "normal" frequency ranges in the fourth decade range from six for men to nine for women (Burgio et al, 1991). **Large variation in the degree of bothersomeness with varying rates of frequency (Fitzgerald et al, 2002) makes a symptomatic diagnosis of BPS/IC based on an absolute number of voids subject to question, and frequency per volume of intake or even the concept of "perception of frequency" as a problem may be more accurate than an absolute number.**

In an effort to define IC so that patients in different geographic areas and under the care of different physicians could be compared, the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) held a workshop in August 1987 at which consensus criteria were established for the diagnosis of IC (Gillenwater and Wein, 1988). These criteria were not meant to define the disease, but rather to ensure that groups of patients included in basic and clinical research studies would be relatively comparable. After pilot studies were carried out to test the criteria, they were revised at another NIDDK workshop a year later (Wein et al, 1990). These criteria are presented in Box 14-2.

Although meant initially to serve only as a research tool, the NIDDK "research definition" became a de facto definition of this disease, diagnosed by exclusion and colorfully termed a "hole in the air" by Hald (George et al, 1986). Certain of the exclusion criteria serve mainly to make one wary of a diagnosis of IC, but should by no means be used for categoric exclusion of such a diagnosis. However, because of the ambiguity involved, these patients should probably be eliminated from research studies or categorized separately. In particular, exclusion criteria 4, 5, 6, 8, 9, 11, 12, 17, and 18 are only relative. The percentage of patients with idiopathic "sensory urgency" (hypersensitivity without decreased compliance or detrusor overactivity [DO]) who have BPS is unclear (Frazer et al, 1990). **The specificity of the finding of bladder glomerulations before or after distention has come into question (Erickson 1995; Waxman et al, 1998; Tomaszewski et al, 2001).** Similarly, the sensitivity of glomerulations is also unknown, but clearly patients with IC symptoms can demonstrate an absence

BOX 14-2 National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) Diagnostic Criteria for Interstitial Cystitis

To be diagnosed with interstitial cystitis, patients must have either glomerulations on cystoscopic examination or a classic Hunner ulcer, and they must have either pain associated with the bladder or urinary urgency. An examination for glomerulations should be undertaken after distention of the bladder under anesthesia to 80 to 100 cm H₂O for 1 to 2 minutes. The bladder may be distended up to two times before evaluation. The glomerulations must be diffuse—present in at least three quadrants of the bladder—and there must be at least 10 glomerulations per quadrant. The glomerulations must not be along the path of the cystoscope (to eliminate artifact from contact instrumentation). The presence of any one of the following excludes a diagnosis of interstitial cystitis:

1. Bladder capacity of greater than 350 mL on awake cystometry using either a gas or liquid filling medium
2. Absence of an intense urge to void with the bladder filled to 100 mL of gas or 150 mL of liquid filling medium
3. The demonstration of phasic involuntary bladder contractions on cystometry using the fill rate just described
4. Duration of symptoms less than 9 months
5. Absence of nocturia
6. Symptoms relieved by antimicrobial agents, urinary antiseptic agents, anticholinergic agents, or antispasmodic agents
7. A frequency of urination while awake of fewer than eight times per day
8. A diagnosis of bacterial cystitis or prostatitis within a 3-month period
9. Bladder or ureteral calculi
10. Active genital herpes
11. Uterine, cervical, vaginal, or urethral cancer
12. Urethral diverticulum
13. Cyclophosphamide or any type of chemical cystitis
14. Tuberculous cystitis
15. Radiation cystitis
16. Benign or malignant bladder tumors
17. Vaginitis
18. Age younger than 18 years

From Wein AJ, Hanno PM, Gillenwater JY. Interstitial cystitis: an introduction to the problem. In: Hanno PM, Staskin DR, Krane RJ, et al, editors. Interstitial cystitis. London: Springer-Verlag; 1990. p. 13–5.

of glomerulations under anesthesia (Awad et al, 1992; Al Hadithi et al, 2002). Bladder ulceration has been considered rare (Sant, 1991). A California series found 20% of patients to have ulceration (Kozioł, 1994). Hunner lesions have been recognized more commonly as more urologists and gynecologists have become aware of the sometimes subtle findings suggesting a lesion and are present in up to 50% of patients in Scandinavia (Logadottir et al, 2012). Specific pathologic findings represent a glaring omission from the criteria because **there is a lack of consensus as to which pathologic findings, if any, are required for, or even suggestive of, a tissue diagnosis (Hanno et al, 1990, 2005a; Tomaszewski et al, 1999, 2001).**

The unexpected use of the NIDDK research criteria by the medical community as a definition of IC led to concerns that many patients with this syndrome might be misdiagnosed. The multicenter Interstitial Cystitis Data Base (ICDB) study through NIDDK accumulated data on 424 patients with IC, enrolling patients from May 1993 through December 1995. Entry criteria were much more

BOX 14-3 Interstitial Cystitis Data Base (ICDB) Study Eligibility Criteria

1. Informed consent to participate in the study
2. Willing to undergo a cystoscopy under general or regional anesthesia when indicated, during the course of the study
3. At least 18 years of age
4. Symptoms of urinary urgency, frequency, or pain for more than 6 months
5. Urinating at least seven times per day, or having some urgency or pain (measured on linear analog scales)
6. No history of current genitourinary tuberculosis
7. No history of urethral cancer
8. No history of bladder malignancy, high-grade dysplasia, or carcinoma in situ
9. Males: no history of prostate cancer
10. Females: no occurrence of ovarian, vaginal, or cervical cancer in the previous 3 years
11. Females: no current vaginitis, clue cells, or *Trichomonas* or yeast infection
12. No bacterial cystitis in the previous 3 months
13. No active herpes in the previous 3 months
14. No antimicrobials for urinary tract infections in previous 3 months
15. Never treated with cyclophosphamide
16. No radiation cystitis
17. No neurogenic bladder dysfunction (e.g., from spinal cord injury, stroke, Parkinson disease, multiple sclerosis, spina bifida, or diabetic cystopathy)
18. No bladder outlet obstruction (determined by urodynamic investigation)
19. Males: no bacterial prostatitis for previous 6 months
20. Absence of bladder, ureteral, or urethral calculi for previous 3 months
21. No urethritis for previous 3 months
22. No urethral dilation, cystometrogram, bladder cystoscopy under full anesthesia, or a bladder biopsy in previous 3 months
23. Never having had an augmentation cystoplasty, cystectomy, cystolysis, or neurectomy
24. No urethral stricture of less than 12 Fr

From Simon LJ, Landis JR, Erickson DR, et al. The Interstitial Cystitis Data Base study: concepts and preliminary baseline descriptive statistics. *Urology* 1997;49:64–75.

symptom driven than those promulgated for research studies (Simon et al, 1997) and are noted in Box 14-3. In an analysis of the defining criteria (Hanno et al, 1999a, 1999b), it appeared the NIDDK research criteria fulfilled their mission. Fully 90% of expert clinicians agreed that patients diagnosed with IC by those criteria in the ICDB indeed had the disorder. However, 60% of patients deemed to have IC by these experienced clinicians would not have met NIDDK research criteria. The ESSIC definition (pelvic pain for longer than 6 months; pressure or discomfort perceived to be related to the urinary bladder accompanied by at least one other urinary symptom such as persistent urge to void or frequency; exclusion of confusable diseases as the cause of the symptoms) (van de Merwe et al, 2008) allows the inclusion of more patients in the IC/BPS syndrome, facilitating diagnosis and treatment in many patients who would otherwise remain undiagnosed (Proaño et al, 2013). Whereas IC symptom and problem indices have been developed and validated (O'Leary et al, 1997; Goin et al, 1998), these are not intended to diagnose or define IC but rather to measure the

severity of symptomatology and monitor disease progression or regression (Moldwin and Kushner, 2004).

IC/BPS is now viewed not only through the paradigm of a chronic pain syndrome that manifests through bladder-related symptoms, but as a syndrome that may not be a true disease of the bladder alone in many patients (Hanno, 2008b). This paradigm is reflected in the current Multidisciplinary Approach to the Study of Chronic Pelvic Pain (MAPP) Research Network (mappnetwork.org), a 10-year ongoing research project of the National Institutes of Health. The subgroup of patients with Hunner lesions do seem to have a primary bladder disease, but their symptom complex is indistinguishable from that of the general IC/BPS population without the aid of endoscopic examination (Nordling et al, 2012). On average, these patients are two decades older than non-Hunner patients and have a smaller bladder capacity when under anesthesia (Logadottir et al, 2012).

Nomenclature and Taxonomy

In accordance with the guidelines of the AUA, this chapter uses the terminology of the International Consultation on Incontinence—*bladder pain syndrome*—but keeps the term *interstitial cystitis* to facilitate recognition and understanding. This change implies that it is the symptoms that drive treatment, and whether *interstitial cystitis* should refer to a distinct subgroup of the bladder pain syndrome (i.e., those with a Hunner lesion) is, as yet, unclear (Hanno et al, 2011; Fall and Peeker, 2013; Hanno et al, 2013).

The literature over the last 170 years has seen numerous changes in description and nomenclature of the disease. The syndrome has variously been referred to as *tic douloureux of the bladder*, *interstitial cystitis*, *cystitis parenchymatosa*, *Hunner ulcer*, *panmural ulcerative cystitis*, *urethral syndrome*, and *painful bladder syndrome* (Skene, 1887; Hunner, 1918; Powell and Powell, 1949; Bourque, 1951; Christmas and Sant, 1997; Teichman et al, 2000; Dell and Parsons, 2004). The term *interstitial cystitis*, which Skene is credited with coining and Hunner brought into common usage, is a misnomer; in many patients not only is there no interstitial inflammation, but histopathologically there may be no inflammation at all (Lynes et al, 1990a; Denson et al, 2000; Tomaszewski et al, 2001; Rosamilia et al, 2003). Focusing exclusively on the urinary bladder, the term *interstitial cystitis* furthermore does not do justice to the condition from both the physician's and the patient's perspectives. The textual exclusiveness ignores the high comorbidity with various pelvic, extrapelvic, and nonurologic symptoms and associated disorders (Clauw et al, 1997) that frequently precede or develop after the onset of the bladder condition (Wu et al, 2006).

With the formal definition of the term *painful bladder syndrome* by the ICS in 2002, the terminology discussion became an intense international focal point (Abrams et al, 2002).

- In Kyoto at the International Consultation on Interstitial Cystitis, Japan (ICICJ) in March 2003, it was agreed that the term *interstitial cystitis* should be expanded to *interstitial cystitis/chronic pelvic pain syndrome* when pelvic pain is at least of 3 months' duration and associated with no obvious treatable condition or pathology (Ueda et al, 2003).
- ESSIC held its first meeting in Copenhagen soon after Kyoto. Nomenclature was discussed but no decision was reached; the meeting concentrated on how to evaluate patients for diagnosis (Nordling et al, 2004).
- At the 2003 meeting of the NIDDK entitled "Research Insights into Interstitial Cystitis," it was concluded that "interstitial cystitis" would ultimately be replaced as a sole name for this syndrome. This was to be a gradual process over several years. At the meeting the condition was referred to as *interstitial cystitis/painful bladder syndrome* in keeping with ICS nomenclature (Hanno et al, 2005b).
- At the 2004 inaugural meeting of the Multinational Interstitial Cystitis Association in Rome, it was concluded that the syndrome should be referred to as *painful bladder syndrome/interstitial cystitis* or *PBS/IC* to indicate an intellectual and taxonomic hierarchy within the acronym (Hanno et al, 2005b).

- The International Consultation on Incontinence in 2004, cosponsored by the ICS and the Société Internationale d’Urologie in association with the World Health Organization, included the syndrome as a part of its consultation. The chapter in the report was entitled “Painful Bladder Syndrome (Including Interstitial Cystitis),” suggesting that the IC formed an identifiable subset within the broader syndrome. Because such a distinction is difficult to define, within the body of the chapter, coauthored by nine committee members and five consultants from four continents, the syndrome was referred to as *PBS/IC* (one inclusive entity) (Hanno et al, 2005a). IC may be a subgroup that encompasses patients with typical histologic and cystoscopic features (Peeker and Fall, 2002a), but what these features are is still controversial and somewhat vague.
- In June 2006 Abrams and colleagues published an editorial focusing on the nomenclature problem (Abrams et al, 2006). They noted, “It is an advantage if the medical term has clear diagnostic features that translate to a known pathophysiologic process so that effective treatment may be given. Unfortunately, the latter is not the case for many of the pain syndromes suffered by patients seen at most pain, gynecologic, and urologic clinics. For the most part these “diagnoses” describe syndromes that do not have recognized standard definitions, yet imply knowledge of a pathophysiologic cause for the symptoms. Unfortunately the terminology used to describe the condition may promote erroneous thinking about treatment on the part of physicians, surgeons and patients. These organ based diagnoses are mysterious, misleading and unhelpful, and can lead to therapies that are misguided or even dangerous.” The editorial went on to note that use of a single pathologic descriptive term (*interstitial cystitis*) for a spectrum of symptom combinations ill serves patients. The umbrella term *painful bladder syndrome* was proposed, with a goal to define and investigate subsets of patients who could be clearly identified within the spectrum of PBS. It would fall within the rubric of CPPS. Affected patients would be identified according to the primary organ that appeared to be affected on clinical grounds. Pain not associated with an individual organ would be described in terms of the symptoms.
- One can see in this the beginnings of a new paradigm that might be expected to change the emphasis of both clinical and basic science research and that removes the automatic presumption that the end organ in the name of the disease should necessarily be the sole or primary target of such research.
- At the major biannual IC research conference in the fall of 2006, held by the NIDDK (“Frontiers in Painful Bladder Syndrome/Interstitial Cystitis”), the ESSIC group was given a block of time in which to present thoughts and conclusions. Because the term *painful bladder syndrome* (1) did not fit into the taxonomy of other pelvic pain syndromes such as urethral or vulvar pain syndromes, (2) as defined by the ICS missed more than a third of affected patients, and (3) is a term open to different interpretations, ESSIC suggested that *painful bladder*

Figure 14-1. Conceptualization of pelvic pain syndrome classification. (From Hanno PM. Interstitial cystitis/painful bladder syndrome/ bladder pain syndrome: the evolution of a new paradigm, Proceedings of the International Consultation on Interstitial Cystitis, Japan: Comfortable Urology Network; 2008. p. 2-9.)

- syndrome* be redesignated as *bladder pain syndrome* followed by a type designation. BPS is indicated by two symbols: The first corresponds to cystoscopy with hydrodistention (CHD) findings (1, 2, or 3, indicating increasing grade of severity), and the second to biopsy findings (A, B, and C, indicating increasing grade of pathologic severity) (Table 14-1). Although neither CHD nor bladder biopsy was prescribed as an essential part of the evaluation, categorizing patients in terms of whether either procedure was performed, and, if so, the results, made it possible to follow patients with similar findings and study each identified cohort to compare natural history, prognosis, and response to therapy (van de Merwe et al, 2008).
- As Baranowski and colleagues conceived it in early 2008, BPS is thus defined as a pain syndrome with a collection of symptoms, the most important of which is pain perceived to be in the bladder (Baranowski et al, 2008). IC is distinguished as an end-organ, visceral-neural pain syndrome, whereas BPS can be considered a pain syndrome that involves the end-organ (bladder) and neurovisceral (myopathic) mechanisms. In IC, one expects end-organ primary pathology. This is not necessarily the case in the broader BPS.
- A didactically very demonstrative way to conceptualize the dawning shift in conception of the condition is with the drawing of a target (Fig. 14-1). There may be many causes of chronic pelvic pain. When a cause cannot be determined, the condition is characterized as pelvic pain syndrome. To the extent that it can be distinguished as urologic, gynecologic, dermatologic, and the like, it is further categorized by organ system. A urologic pain syndrome can sometimes be further differentiated based on the site of perceived pain. Bladder, prostate, testicular, and epididymal pain syndromes follow. Finally, types of BPS can be further defined as IC or simply

categorized by ESSIC criteria. Patient groups have expressed their concerns with regard to any nomenclature change that potentially drops the term *interstitial cystitis* because the U.S. Social Security Administration and private insurers recognize IC but not the term *bladder pain syndrome*, and benefits potentially could be adversely affected. Whether the term *interstitial cystitis*, as difficult as it is to define and as potentially misleading as it is with regard to cause and end-organ involvement, should be maintained is a subject of ongoing controversy (Hanno and Dmochowski, 2009).

KEY POINTS: DEFINITION

- The *painful bladder disease complex* includes a large group of patients with bladder and/or urethral and/or pelvic pain, irritative voiding symptoms, and sterile urine cultures, many with specific identifiable causes.
- *Bladder pain syndrome* comprises a part of this complex and is a clinical diagnosis based primarily on chronic symptoms of pain perceived by the patient to emanate from the bladder and/or pelvis associated with urinary urgency or frequency in the absence of other identified causes for the symptoms.
- Whether the older term *interstitial cystitis* should refer to a distinct subgroup of BPS (i.e., those with Hunner lesions) is, as yet, unclear.

Urgency is a common complaint of this group of patients. The ICS definition of urgency (Abrams et al, 2002), “the complaint of a sudden compelling desire to pass urine, which is difficult to defer,” could be interpreted as compatible with either DO or BPS/IC depending on the weight one attaches to the word *sudden*. There are those who see hypersensitivity or sensory urgency as bridging both overactive bladder and BPS/IC (Haylen et al, 2007; Yamaguchi et al, 2007), and the issue has been nicely addressed by Homma (2008). Pain and pressure are more involved in the frequency of BPS/IC, and fear of incontinence seems the reason for the urgency of overactive bladder (Abrams, 2005). Although BPS patients may have significantly higher voiding frequencies, smaller voided volumes, and narrower ranges of voided volume compared with overactive bladder patients (Kim et al, 2014), one cannot distinguish between the two syndromes based on a voiding diary. Urgency is not required to define BPS/IC, as it would tend to obfuscate the borders of overactive bladder and BPS/IC, and is unnecessary for definition purposes. The term *urgency* as it is comprehended by patients is not a well-defined and commonly understood symptom that can be used to clearly discriminate between BPS/IC and overactive bladder (Clemens et al, 2011). Figure 14-2 (Abrams et al, 2005)

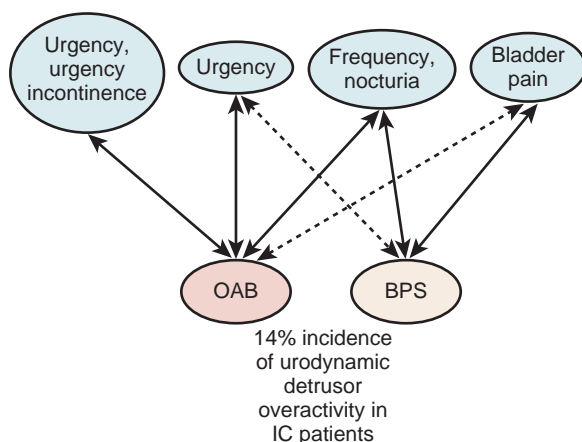

Figure 14-2. Overactive bladder (OAB) and its relationship to bladder pain syndrome (BPS). IC, interstitial cystitis. (From Abrams P, Hanno P, Wein A. Overactive bladder and painful bladder syndrome: there need not be confusion. *Neurourol Urodyn* 2005;24:149–50.)

is a graphic depiction of one view of the relationship between these two sometimes confused conditions. The 14% incidence of urodynamic DO in the BPS/IC patients (Nigro et al, 1997a) is probably close to what one might expect in the general population if studied urodynamically (Salavatore et al, 2003).

Still, there remains some ambiguity, and further research is necessary with regard to urgency (Hanno et al, 2009). Studies are hampered by the fact that patients tend to use words to describe lower urinary tract symptoms, but attribute different meanings to the words than do physicians and researchers (Digesu et al, 2008). An analysis of urgency by the University of Maryland group reported that 65% of patients with BPS experienced an urge to urinate to relieve pain, with 46% agreeing that they had an urge to relieve pain and not to prevent incontinence. Still, 21% reported that urgency arose from fear of impending incontinence and that this sensation was not present before the onset of BPS symptoms (Diggs et al, 2007). In some patients the term connotes an intensification of the normal urge to void, and in others it is a different sensation (Blaivas et al, 2009).

New efforts to phenotype the chronic urologic pain syndromes (BPS and chronic nonbacterial prostatitis and CPPS in men) are currently being explored (Shoskes et al, 2009). One of these is the MAPP Research Network, a 10-year ongoing research project of the National Institutes of Health (mappnetwork.org). Patients with Hunner lesions would seem to have a more bladder-centric disorder and are less likely to have comorbid conditions (Peters et al, 2011). The hope is that looking at psychological, physical, and organ-specific parameters of affected patients, and specifically focusing on associated disorders, will aid in proper selection of therapeutic agents that may have selective specificity for different symptom constellations, and also may improve productivity and results of research on etiology, prognosis, and new therapeutic agents.

KEY POINTS: URGENCY

- Urgency has been defined as the complaint of a sudden compelling desire to pass urine, which is difficult to defer.
- What the patient believes precipitates the sensation is not a part of the definition, and this has resulted in some ambiguity. Fear of incontinence is more consistent with overactive bladder, whereas pressure, pain, or discomfort suggests BPS.

EPIDEMIOLOGY

Prevalence

Epidemiology studies of BPS/IC have been hampered by many problems (Bernardini et al, 1999). The lack of an accepted definition, the absence of a validated diagnostic marker, and questions regarding etiology and pathophysiology make much of the literature difficult to interpret. This is most apparent when one looks at the variation in prevalence reports in the United States and around the world. These range from 1.2 to 4.5 per 100,00 females in Japan (Ito et al, 2000) to a figure in American women of 20,000 per 100,000 according to a questionnaire-based study (Parsons and Tatsis, 2004). Tea consumption and smoking were purported to be risk factors in a large Swedish twin study (Tettamanti et al, 2011); however the per capita consumption of tea in the United Kingdom is more than double that of the vast majority of the world's population, and no study reports a higher prevalence of BPS in that country.

It has been estimated that the prevalence in the population of chronic pain from benign causes is at least 10% (Verhaak et al, 1998). Numerous case series have, until recently, formed the basis of epidemiologic information regarding BPS/IC. Farkas and associates discussed IC in adolescent girls (Farkas et al, 1977). Hanash and Pool reviewed their experience with IC in men (Hanash and Pool, 1969). Geist and Antolak reviewed and added to reports of

disease occurring in childhood (Geist and Antolak, 1970). A childhood presentation is extremely rare and must be differentiated from the much more common and benign-behaving extraordinary urinary frequency syndrome of childhood, a self-limited condition of unknown cause (Koff and Byard, 1988; Robson and Leung, 1993). Nevertheless, there is a small cohort of children with chronic symptoms of bladder pain, urinary frequency, and sensory urgency in the absence of infection who have been evaluated with urodynamics, cystoscopy, and bladder distention and have findings consistent with the diagnosis of BPS/IC. In a review of 20 such children by Close and colleagues, the median age of onset was younger than 5 years, and the vast majority of patients had long-term remissions with bladder distention (Close et al, 1996).

A study conducted at the Scripps Research Institute (Koziol et al, 1993) included 374 patients at Scripps as well as some members of the Interstitial Cystitis Association, the large patient support organization. The findings of a more recent but similar study in England (Tincello and Walker, 2005) concurred with the Scripps findings of urgency, frequency, and pain in the vast majority of these patients, devastating effects on quality of life, and often unsuccessful attempts at therapy with a variety of treatments. Although such reviews provide some information, they would seem to be necessarily biased by virtue of their design.

Several population-based studies have been reported in the literature (Fig. 14-3), and these studies tend to support the reviews of selected patients or from individual clinics and the comprehensive follow-up case-control study by Koziol (1994). The first population-based study (Oravisto, 1975) included "almost all the patients with interstitial cystitis in the city of Helsinki." This superb, brief report from Finland surveyed all diagnosed cases in a population approaching 1 million. The prevalence of the disease in women was 18.1 per 100,000. The joint prevalence in both sexes was 10.6 cases per 100,000. The annual incidence of new cases in women was 1.2 per 100,000. Severe cases accounted for about 10% of the total. Ten percent of cases were in men. The disease onset was typically subacute rather than insidious, and full development of the classic symptom complex occurred over a relatively short time. IC does not progress continuously, but usually reaches its final stage rapidly (within 5 years in the Koziol study (Koziol et al, 1993) and then continues without significant change in symptomatology. Subsequent major deterioration was found by Oravisto to be unusual. The duration of symptoms before diagnosis was 3 to 5 years in the Finnish study. Analogous figures in a classic U.S. paper a quarter of a century earlier were 7 to 12 years (Hand, 1949).

Another early population study, this in the United States, first demonstrated the potential extent of what had been considered a very rare disease (Held et al, 1990). The following population groups were surveyed: (1) 127 board-certified urologists who completed a random survey; (2) 64 IC patients selected by the surveyed urologists and divided among the last patient with IC seen and the last patient with IC diagnosed; (3) 904 female patients belonging to the Interstitial Cystitis Association; and (4) 119 persons from the

U.S. population who completed a random phone survey. This 1987 study found the following:

1. 43,500 to 90,000 diagnosed cases of IC in the United States (twice the Finnish prevalence)
2. Up to a fivefold increase in IC prevalence if all patients with painful bladder and sterile urine had been given the diagnosis, yielding up to half a million possible cases in the United States
3. Median age of onset 40 years
4. Late deterioration in symptoms unusual
5. 50% temporary spontaneous remission rate, mean duration 8 months
6. 10 times higher incidence of childhood bladder problems in IC patients versus controls
7. Double the incidence of a history of urinary tract infection versus controls
8. 14% of IC patients were Jewish (15% in Koziol sample [Koziol, 1994]) versus 3% Jewish individuals in the general population sample
9. Lower quality of life than in dialysis patients
10. Costs including lost economic production in 1987 of \$427 million

Other population studies followed. Jones and colleagues obtained their data from self-report of a previous diagnosis of IC in the 1989 National Household Interview Survey (Jones and Nyberg, 1997). The survey estimated that 0.5% of the population, or more than 1,000,000 people in the United States, reported having had a diagnosis of IC. There was no verification of this self-report by medical records. Bade and colleagues performed a physician questionnaire-based survey in the Netherlands that yielded an overall prevalence of 8 to 16 per 100,000 females, with diagnosis heavily dependent on pathology and presence of mast cells (Bade et al, 1995). This prevalence in females compares with 4.5 per 100,000 in Japan (Ito et al, 2000). The Nurses' Health Study I and II (Curhan et al, 1999) showed a prevalence of IC of 52 to 67 per 100,000 in the United States, twice the prevalence in the Held study (Held et al, 1990) and threefold higher than in the Netherlands (Bade et al, 1995). It improved on previous studies by using a large sample derived from a general population and careful ascertainment of the diagnosis. If the 6.4% confirmation rate of these studies were applied to the Jones and colleagues National Health Interview Survey data, the prevalence estimates of the two studies would be nearly identical.

The most sophisticated population-based prevalence study was conducted by the Rand Corporation. With use of a case definition with an 83% specificity, a random sample of 146,231 households was contacted by telephone and 12,752 women completed the questionnaire; 2.7% met the high-specificity definition of BPS. Less than 10% of these women had a clinical diagnosis of BPS/IC. The figures correspond to 3.3 million women in the United States aged 18 or older with symptoms compatible with the diagnosis (Berry et al, 2011). When the same methodology was applied to men, the findings suggested that 1.9% of adult U.S. males have symptoms of IC/BPS, higher than the weighted prevalence of chronic prostatitis and CPPS (Suskind et al, 2013a). The Rand prevalence data are very high, yet the methodology is exceptionally sound for a population-based prevalence study (Konkle et al, 2012).

Leppilahti and colleagues used the O'Leary-Sant interstitial cystitis symptom and problem index (never validated for making a diagnosis per se) to select women with IC symptoms from the Finnish population register. Of 1331 respondents, 32 had moderate or severe symptoms involving a suspicion of BPS/IC (symptom score 7 or higher). Of 21 who consented to clinical evaluation, 7 had probable or possible BPS/IC. Corrected estimates yielded a prevalence of 300 per 100,000 women (Leppilahti et al, 2002, 2005). Similar studies without clinical confirmation suggested prevalence in Austrian women of 306 per 100,000 (Temml et al, 2007) and in Japanese women of 265 per 100,000 (Inoue et al, 2009). With use of the Bristol Female Lower Urinary Tract Symptoms questionnaire, prevalence of BPS symptoms of 100 per 100,000 Fuzhou Chinese women was reported (Song et al, 2009).

Figure 14-3. Prevalence of bladder pain syndrome per 100,000 females in reported studies from around the world. See text for details.

Roberts and colleagues, using a physician diagnosis as the arbiter of IC, found annual incidence in Olmsted County, Minnesota of 1.6 per 100,000 in women and 0.6 per 100,000 in men, a figure remarkably similar to that of Oravisto in Helsinki (Roberts et al, 2003). The cumulative prevalence by age older than 80 years in the Minnesota study was 114 per 100,000, a figure comparable to that in the Nurses' Health Study if one takes into account the younger age group in the Curhan data. Clemens calculated a prevalence of diagnosed disease in a managed care population of 197 per 100,000 women and 41 per 100,000 men, but when the diagnosis was tested by eliminating those who had not been evaluated with endoscopy or in whom exclusionary conditions existed, the numbers dropped considerably (Clemens et al, 2005). The Boston Area Community Health (BACH) Survey estimated a prevalence of BPS symptoms of 1% to 2% of the population depending on the definition used (Clemens et al, 2007). A population-based study in Korea found a prevalence in women of 0.26% (Choe et al, 2011). A Japanese study estimated the incidence of hospital admissions related to IC/BPS at 1.35 per 100,000 person-years (Sugihara et al, 2012).

With regard to office visits to practices with an interest in urologic problems, 2.8% of patients in Canadian urologist offices had BPS/IC (Nickel et al, 2005b), and probable BPS/IC was found in 0.57% of patients in a primary care office in Michigan (Rosenberg and Hazzard, 2005).

Until the Rand study, a reasonable prevalence estimate (recognizing that a consistent definition of the condition had not been used in epidemiologic studies) appeared to be about 300 per 100,000 in females, and in males 10% to 20% of the estimate in females. It now appears the problem may be 10 times greater.

Whether the considerable variability in prevalence in studies within the United States and around the world is related to methodology or true differences in incidence is an important question yet to be answered. One reason may be that pain that the patient perceives to be related to the bladder is a problematic concept, because most patients have different reasons for reaching that conclusion (Warren et al, 2011b). It is clear that the prevalence of BPS/IC symptoms is much greater than the prevalence of a physician diagnosis of the disease (Clemens et al, 2007). Familial occurrence of BPS/IC has been reported (Dimitrakov, 2001). A hereditary aspect to incidence has been suggested by Warren in a pioneering study. He found that adult female first-degree relatives of patients with IC may have a prevalence of IC 17 times that found in the general population. This, together with previously reported evidence showing a greater concordance of IC among monozygotic than dizygotic twins, suggests but does not prove a genetic susceptibility to IC that could partially explain the discord in prevalence rates in different populations (Warren et al, 2001b, 2004).

KEY POINT: PREVALENCE

- Prevalence studies show wide variation; however, more modern studies of the prevalence of BPS/IC per 100,000 women tend to show higher values.

Prevalence of BPS/IC per 100,000 Women

Characteristics and Natural History

Before the Rand study (Suskind et al, 2013a), most studies had shown a female-to-male preponderance of 5:1 or greater (Clemens et al, 2005; Hanno et al, 2005a). In the absence of a validated marker, it is often difficult to distinguish BPS/IC from CPPS (nonbacterial prostatitis, prostatodynia) that affects males (Forrest and Schmidt, 2004), and the percentage of men with BPS/IC may actually be higher (Miller et al, 1995, 1997; Novicki et al, 1998). Men tend to be diagnosed at an older age and have a higher percentage of Hunner lesions in the case series reported (Novicki et al, 1998; Roberts et al, 2003). Costs of the disorder are not insignificant and can range from \$4000 to \$7000 dollars per year, not including lost wages, costs preceding diagnosis, costs of alternative therapies, and costs attributable to misdiagnosis (Clemens et al, 2008c, 2009b).

Patients with BPS/IC analyzed across a wide spectrum of ages at time of diagnosis show different symptom profiles. Those diagnosed at the youngest ages experienced significantly more urinary urgency, frequency, dysuria, dyspareunia, and pain in their external genitalia. Older patients had a higher incidence of nocturia, urinary incontinence, and Hunner lesions (Rais-Bahrami et al, 2012). Patients with mild disease symptoms at onset appear to show symptom stability at 3 years, whereas those with concomitant chronic fatigue syndrome at symptom onset tend to show symptom progression of BPS/IC over time (Warren et al, 2013a).

The ICDB cohort of patients has been carefully studied, and the findings seem to bear out those of other epidemiologic surveys (Proper et al, 2000). Patterns of change in symptoms with time suggest regression to the mean and an intervention effect associated with the increased follow-up and care of cohort participants. Although all symptoms fluctuated, there was no evidence of significant long-term change in overall disease severity. The data suggest that BPS/IC is a chronic disease, and no current treatments have a significant impact on symptoms over time in the majority of patients. Quality-of-life studies suggest that BPS/IC patients are six times more likely than individuals in the general population to cut down on work time because of health problems, but only half as likely to do so as patients with arthritis (Shea-O'Malley and Sant, 1999). There is an associated high incidence of comorbidity including depression, chronic pain, and anxiety and overall mental health issues (Michael et al, 2000; Rothrock et al, 2002; Hanno et al, 2005a). Disability may be partially explained by the impact of negative affect and catastrophizing (Katz et al, 2013). There seems to be no effect on pregnancy outcomes (Onwude and Selo-Ojeme, 2003).

Female patients with BPS/IC seem to report significant dyspareunia and other manifestations of sexual dysfunction. All domains of female sexual function including sexually related distress, desire, and orgasm frequency can be affected (Ottem et al, 2007; Peters et al, 2007b). Sexual function is an important predictor of physical quality of life and was the only strong predictor of mental quality of life in one study of patients with severe BPS/IC (Nickel et al, 2007).

The BACH Survey (Link et al, 2008) showed an overall prevalence of symptoms suggestive of BPS of 2%, with twice as many women as men affected. It was most common among middle-aged respondents, with an earlier peak in women. It was most common among minorities and those of lower socioeconomic status (SES), and SES seemed to overcome any effect of race or ethnicity. Emotional, sexual, and physical abuse was shown to be a risk factor in the BACH Survey (Link and Luftey, 2007), and this has been borne out in other studies. A Michigan study compared a control group of 464 women with 215 BPS/IC patients and found that 22% of the control group had experienced abuse versus 37% of the patient group (Peters et al, 2007b). Those with a history of sexual abuse may have more pain and fewer voiding symptoms (Seth and Teichman, 2008). How reliable these data are is not clear, and it would be wrong to jump to any conclusions about abuse in an individual patient. However, practitioners need to have sensitivity to the possibility of an abusive relationship history in all pain

patients, and BPS patients in particular. When patients are found to have multiple diagnoses, the rate of previous abuse also increases, and these patients may need referral for further counseling at a traumatic stress center (Fenton et al, 2008).

KEY POINTS: NATURAL HISTORY

- The female-to-male preponderance had been estimated at 5:1. Newer data suggest the prevalence may be similar in males and females.
- Symptoms tend to fluctuate, with the majority of patients showing no long-term deterioration.
- There is no deleterious effect on pregnancy outcomes.
- Men are diagnosed at an older age and have a higher prevalence of Hunner lesions.
- Quality of life in almost all domains is significantly affected.

Associated Disorders

Knowledge of associated diseases is relevant for the clues it engenders with regard to cause and possible treatment of this enigmatic pain syndrome. It is well known that patients with chronic pain syndromes including chronic fatigue syndrome, fibromyalgia, and temporomandibular disorder share key symptoms and can often develop overlapping conditions including chronic pelvic pain (Aaron and Buchwald 2001; Aaron et al, 2001). Female patients with BPS/IC report significantly more nonpain symptoms and pain outside the pelvis than control female urology patients. In contrast to males with CPPS and nonbacterial prostatitis, females with BPS/IC are more likely to endorse multiple bothersome, medically unexplained symptoms across multiple organ systems (Lai et al, 2012). Bladder symptoms do not uniformly predate the nonbladder symptoms (Clemens et al, 2012). The number of functional somatic syndromes is perhaps the strongest risk factor for development of other non-bladder pain syndromes in the BPS/IC population. This is especially true for irritable bowel syndrome, fibromyalgia, and chronic fatigue syndrome (Warren et al, 2013a). These associated syndromes have an equivalent negative impact to BPS/IC in terms of quality of life (Suskind et al, 2013b).

In a case-control study Erickson found that patients with IC had higher scores than controls for pelvic discomfort, backache, dizziness, chest pain, aches in joints, abdominal cramps, nausea, palpitations, and headache (Erickson et al, 2001). Buffington theorizes that a common stress-response pattern of increased sympathetic nervous system function in the absence of comparable activation of the hypothalamic-pituitary-adrenal axis may account for some of these related symptoms (Buffington, 2004). Both depression and panic attacks have a high prevalence in patients with BPS/IC symptoms (Watkins et al, 2011). It has been suggested that panic disorder, a diagnosis associated with some BPS/IC patients (Clemens et al, 2008a), may sometimes be a part of a familial syndrome that includes IC, thyroid disorders, and other disorders of possible autonomic or neuromuscular control (Weissman et al, 2004; Subaran et al, 2012). Depression has been associated with BPS/IC in both men and women (Clemens et al, 2008a; Hall et al, 2008), but whether this is an association or effect of the disorder is uncertain (FitzGerald et al, 2007).

Newly diagnosed patients are most concerned with the possibility that BPS/IC could be a forerunner of bladder carcinoma. Until recently, no reports have ever documented a relationship to suggest that IC is a premalignant lesion. Utz and Zincke discovered bladder cancer in 12 of 53 men treated for IC at the Mayo Clinic (Utz and Zincke, 1974). Initial misdiagnosis was likely. Three of 224 women were eventually diagnosed with bladder cancer. Four years later, additional cases were reported (Lamm and Gittes, 1977). Tissot and colleagues reported that 1% of 600 patients previously diagnosed as having IC were found to have transitional cell carcinoma as the cause of symptoms (Tissot et al, 2004). Somewhat ominously, 2 of these patients had no hematuria. In all patients, irritative symptoms resolved after treatment of the malignancy. From this experience has

come the dictum that all patients with presumed IC should undergo cystoscopy, urine cytology, and bladder biopsy of any suspicious lesion to be sure that a bladder carcinoma is not masquerading as BPS/IC. It would seem that in the absence of microhematuria, and with negative cytology, the risk of missing a cancer is negligible, but not zero. A study from Taiwan reports a 2.95 relative risk of developing bladder cancer in BPS/IC patients compared with controls based on data analyzed from the Taiwan National Health Insurance Program (Keller et al, 2013b). This leaves the question still unresolved.

A large-scale survey of 6783 individuals diagnosed by their physicians as having BPS/IC studied the incidence of associated disease in this population (Alagiri et al, 1997). Data from the 2405 responders were validated by comparison with 277 nonresponders (Fig. 14-4). Allergies were the most common association, with over 40% affected. Allergy was also the primary association in Hand's study (Hand, 1949). Thirty percent of patients had a diagnosis of irritable bowel syndrome, a finding confirming that of Koziol (1994). Altered visceral sensation has been implicated in irritable bowel syndrome in that these patients experience intestinal pain at intestinal gas volumes that are lower than those that cause pain in healthy persons (Lynn and Friedman, 1993), strikingly similar to the pain on bladder distention in IC.

Fibromyalgia, another disorder frequently considered functional because no specific structural or biochemical cause has been found, is also overrepresented in the BPS/IC population. This is a painful nonarticular condition predominantly involving muscles; it is the commonest cause of chronic, widespread musculoskeletal pain. It is typically associated with persistent fatigue, nonrefreshing sleep, and generalized stiffness. Women are affected at least 10 times more often than men (Consensus document on fibromyalgia, 1993). The association is intriguing because both conditions have similar demographic features, modulating factors, associated symptoms, and response to tricyclic compounds (Clauw et al, 1997; Chelmsky et al, 2012).

Diagnosed vulvodynia, migraine headaches, endometriosis, chronic fatigue syndrome, incontinence, and asthma had similar prevalence as in the general population. Several publications have noted an association between BPS/IC and systemic lupus erythematosus (SLE) (Fister, 1938; Boye et al, 1979; de la Serna and Alarcon-Segovia, 1981; Weisman et al, 1981; Meulders et al, 1992). The question has always been whether the bladder symptoms represent an association of these two disease processes or rather are a manifestation of lupus involvement of the bladder (Yukawa et al, 2008) or even a myelopathy with involvement of the sacral cord in a small group of these patients (Sakakibara et al, 2003). The beneficial response of the cystitis of SLE to steroids (Meulders et al, 1992) tends to support the latter view. No association with discoid lupus has been demonstrated (Jokinen et al, 1972b). Overall, the incidence of collagen-vascular disease in the IC population is low. Parsons found only 2 of 225 consecutive IC patients to have a history of autoimmune disorder (Parsons, 1990).

The National Health Insurance Research Database of the Taiwan National Health Insurance Programme has yielded data on many associations with BPS, some of which await confirmation from further population-based research. These include depression, anxiety, urinary calculus, erectile dysfunction, reflux esophagitis, coronary heart disease, obstructive sleep apnea, rheumatoid arthritis, and ischemic stroke (Chung et al, 2013, 2014a, 2014b, 2015; Kang et al, 2013; Keller et al, 2013a, 2013c, 2013d; Chen et al, 2014b). A study using this database has looked at a multitude of other illnesses using a logistic regression analysis, and only metastatic cancer did not show a statistically higher prevalence rate in BPS patients, making the data somewhat difficult to interpret (Keller et al, 2012).

Inflammatory bowel disease was found in over 7% of the IC population Alagiri studied, a figure 100 times higher than in the general population and never corroborated by other epidemiologic studies (Alagiri et al, 1997). Although unexplained at this time, abnormal leukocyte activity has been implicated in both conditions (Bhone et al, 1962; Kontras et al, 1971).

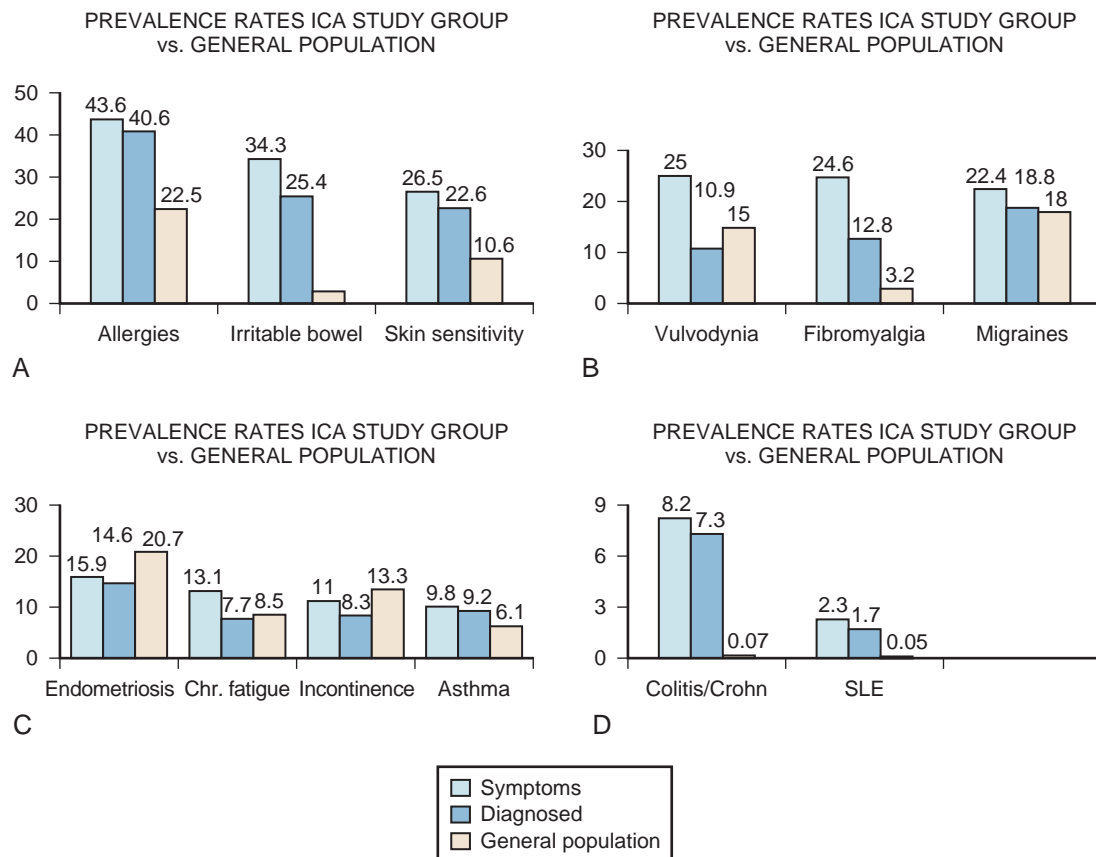

Figure 14-4. A through D, Comparison of disease prevalence rates among the Interstitial Cystitis Association (ICA) study group patients who report symptoms of a disorder, who have been diagnosed with a disorder, and the general population. Chr., chronic; SLE, systemic lupus erythematosus. (From Alagiri M, Chottiner S, Ratner V, et al. Interstitial cystitis: unexplained associates with other chronic pain syndromes. *Urology* 1997;49[Suppl. 5A]:52–7.)

The University of Maryland group sought antecedent nonbladder syndromes in 313 patients with incident BPS/IC and compared them with 313 matched controls (Warren et al, 2009). They found 11 antecedent syndromes were more often diagnosed in those with BPS/IC, and most syndromes appeared in clusters. The most prominent cluster (45%) comprised fibromyalgia–chronic widespread pain, chronic fatigue syndrome, sicca syndrome, and/or irritable bowel syndrome. Most of the other syndromes and identified clusters were associated with it. These researchers found probable chronic fatigue syndrome in 20% of BPS/IC patients, probable fibromyalgia in 22%, and probable irritable bowel in 27% of the BPS patients. Far fewer had physician-reported diagnoses of these syndromes, and odds ratios (ORs) for BPS/IC versus controls were 2.5 to 2.9. BPS/IC was significantly associated with previous female hormone use, a history of fewer pregnancies (in premenopausal women), and antecedent nonbladder syndromes (Warren et al, 2011a). Perhaps not surprisingly, in the month before the onset of BPS/IC, the approximated annual incidence of nonbladder pelvic surgeries was 15 times higher and of hysterectomy 25 times higher than the incidences in previous years and similarly higher than controls. The rate declined to preindex levels over the first 2 years of BPS/IC (Warren et al, 2013b). Although one could postulate that the surgery was an initiating factor, it may be more likely that the pelvic pain from undiagnosed BPS was what prompted the pelvic surgery in the first place.

Study of a managed care database in Portland, Oregon revealed that patients coded for gastritis (OR = 12.2), child abuse (OR = 9.3), fibromyalgia (OR = 3.0), anxiety disorder (OR = 2.8), headache (OR = 2.5), or depression (OR = 2.0) were commonly diagnosed with BPS/IC (Clemens et al, 2008b).

Women with BPS experience very high levels of sexual dysfunction (Bogart et al, 2011). An unexplained disorder that has been associated with IC is vulvodynia with focal vulvitis (Gardella et al, 2011; Reed et al, 2012). Vulvar vestibulitis syndrome is a constellation of symptoms and findings involving and limited to the vulvar vestibule and consisting of (1) severe pain on vestibular touch to attempted vaginal entry, (2) tenderness to pressure localized within the vulvar vestibule, and (3) physical findings confined to vulvar erythema of various degrees (Marinoff and Turner, 1991). McCormack reported on 36 patients with focal vulvitis, 11 of whom also had IC (McCormack, 1990). Fitzpatrick added 3 more patients (Fitzpatrick et al, 1993). Vulvodynia is associated not only with BPS/IC but also with irritable bowel syndrome and fibromyalgia (Nguyen et al, 2013). The concordance of these noninfectious inflammatory syndromes involving the tissues derived from the embryonic urogenital sinus and the similarity of the demographics argue for a common cause.

An association has been reported between IC and Sjögren syndrome (SS), an autoimmune exocrinopathy with a female preponderance manifested by dry eyes, dry mouth, and arthritis, but which can also include fever, dryness, and gastrointestinal and lung problems. Van de Merwe and colleagues (1993) investigated 10 IC patients for the presence of SS. Two patients had both keratoconjunctivitis sicca and focal lymphocytic sialoadenitis, allowing a primary diagnosis of SS. Only 2 patients had neither finding. He later reported an incidence of 28% of SS in patients with IC (van de Merwe et al, 2003). The incidence of symptoms of BPS/IC in patients with SS has been estimated to be up to 5% (Leppilähti et al, 2003). Patients with SS may have bladder symptoms from DO, and each patient requires careful individual evaluation before a diagnosis of BPS/IC is made (Lee et al, 2011a).

A negative correlation with diabetes has been noted (Parsons, 1990; Koziol, 1994; Warren et al, 2009). Although patients with multiple pain locations (increased pain phenotype) may have poorer psychosocial adjustment and diminished quality of life (Tripp et al, 2012), one cannot distinguish patients with Hunner lesions from those without Hunner lesions with regard to the number of painful areas or the location of pain (Killinger et al, 2013).

Further epidemiologic studies are warranted, because the epidemiology of this disorder may ultimately yield as many clues into cause and treatment as other avenues of research. The heterogeneity of causes and symptoms of CPPS suggests that proper clinical phenotyping could foster the development of better treatments for individual phenotypes and more successful treatments for all affected patients (Baranowski et al, 2008; Shoskes et al, 2009).

KEY POINTS: ASSOCIATED DISORDERS

- Look for symptoms of the following disorders, which may be associated with some cases of BPS: depression, SS, irritable bowel syndrome, allergies, fibromyalgia, chronic fatigue syndrome, inflammatory bowel disease, focal vulvitis.
- BPS has not been considered a premalignant condition.

ETIOLOGY

It is likely that BPS/IC has a multifactorial cause that may act predominantly through one or more pathways, resulting in the typical symptom complex (Holm-Bentzen et al, 1990; Mulholland and Byrne, 1994; Erickson, 1999; Levander, 2003; Keay et al, 2004b) (Fig. 14-5). There are an abundance of theories regarding

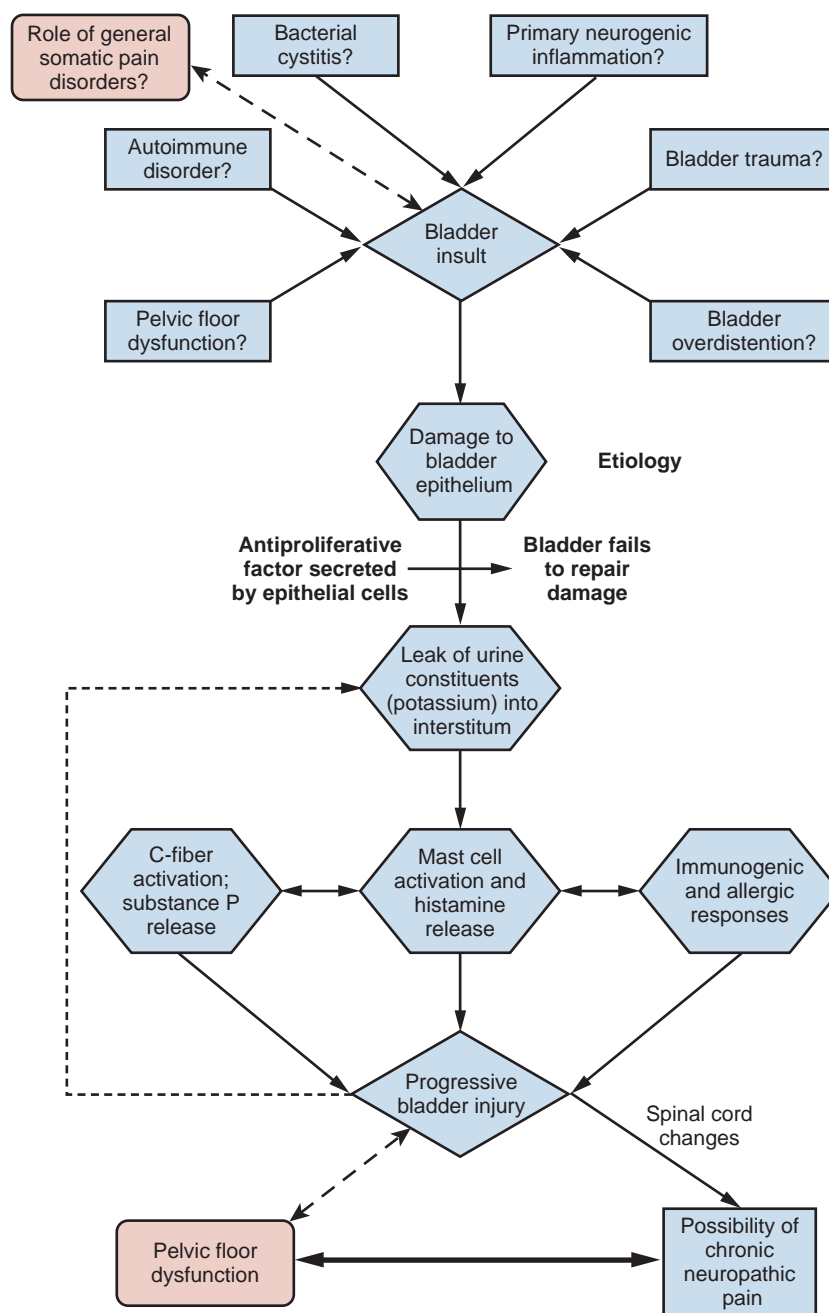

Figure 14-5. Hypothesis of causative cascade of bladder pain syndrome. (From Hanno P, Dinis P, Lin A, et al. Bladder pain syndrome. In: Abrams P, Cardozo L, Khoury S, et al, editors. Incontinence. Paris: International Consultation on Urological Diseases/European Association of Urology; 2013. p. 1583–649.)

its pathogenesis, but confirmatory evidence gleaned from clinical practice has proven sparse. Among numerous proposals that are further explored in this section are “leaky epithelium,” mast cell activation, and neurogenic inflammation, or some combination of these and other factors leading to a self-perpetuating process resulting in chronic bladder pain and voiding dysfunction (Elbadawi, 1997). Irritable bowel syndrome, fibromyalgia, chronic fatigue syndrome, and various other chronic pain disorders may precede or follow the development of BPS/IC in some patients (Kim and Chang, 2012), but development of associated syndromes is not inevitable by any means, and their relationship to the cause is currently unknown (Warren et al, 2009). It has been postulated that neural cross-talk in the dorsal root ganglia, in the spinal cord, and at the level of the brain might play a role in the development of chronic pain disorders and their clinical associations through central sensitization (Furuta et al, 2012a). In rats, injection of hydrochloric acid into the gluteus can induce plantar hypersensitivity and urinary frequency for up to 2 weeks after the injection (Furuta et al, 2012b).

A discussion of animal models and the possible role of infection, autoimmunity, inflammation, mast cells, histamine, epithelial permeability, antiproliferative factor (APF), neurogenic factors, cross-sensitization, urine abnormalities, genetic factors, stress, and pelvic floor dysfunction can be found on the Expert Consult website.

PATHOLOGY

Pathology can be consistent with the diagnosis of BPS, but there is no histology pathognomonic of this syndrome. The role of histopathology in the diagnosis of BPS is primarily one of excluding other possible diagnoses. One must rule out carcinoma and carcinoma in situ, eosinophilic cystitis, and tuberculous cystitis, as well as any other entities with a specific tissue diagnosis (Hellstrom et al, 1979; Johansson and Fall, 1990; Tsiropoulos et al, 2006).

Although earlier reports described a chronic, edematous pancystitis with mast cell infiltration, submucosal ulcerations, and involvement of the bladder wall and chronic lymphocytic infiltrate (Smith and Dehner, 1972; Jacobo et al, 1974), these were cases culled from patients with severe disease and not representative of the majority of cases currently diagnosed. The pathologic findings in BPS are not consistent. There has been a great variation in the reported histologic appearance of biopsy specimens from BPS patients, and even variation among samples taken from the same patients over time (Gillenwater and Wein, 1988).

Lépinard and colleagues (1984) reported a pancystitis affecting the three layers of bladder wall. In nonulcerative disease the vesical wall was never normal, epithelium being thinned and muscle being affected. Johansson and Fall looked at 64 patients with ulcerative disease and 44 with nonulcerative IC (Johansson and Fall, 1990). The former group had mucosal ulceration and hemorrhage, granulation tissue, intense inflammatory infiltrate, elevated mast cell counts, and perineural infiltrates. The nonulcerative group, despite having the same severe symptoms, had a relatively unaltered mucosa with a sparse inflammatory response, the main feature being multiple, small mucosal ruptures and suburothelial hemorrhages that were noted in a high proportion of patients. As these specimens were almost all taken immediately after hydrodistention, how much of the admittedly minimal findings in the nonulcerative group was purely iatrogenic is a matter of speculation.

Completely normal biopsy specimens are not uncommon in the nonulcerative BPS group (Johansson and Fall, 1994). Transition from nonulcerative to ulcerative BPS is a rare event (Fall et al, 1987), and pathologically the two types of IC may be completely separate entities. Although mast cells are more commonly seen in the detrusor in ulcerative BPS (Holm-Bentzen et al, 1987a), they are also common in patients with idiopathic bladder instability (Moore et al, 1992). Mastocytosis in BPS is best documented by tryptase immunocytochemical staining (Theoharides et al, 2001). Larsen and colleagues recommend taking biopsy specimens from

the detrusor of patients with suspected BPS and examining them with tryptase-stained 3-micron-thick sections, with every seventh section used for quantification. They consider 27 mast cells/mm² indicative of mastocytosis (Larsen et al, 2008). Despite attempts to develop a diagnostic algorithm based on the detrusor-to-mucosa mast cell ratio and nerve fiber proliferation (Hofmeister et al, 1997), mast cell counts per se have no place in the differential diagnosis of this clinical syndrome.

Mast cells could be valuable in clinical phenotyping, but as yet that is unproven. Mast cells trigger inflammation that is associated with local pain, but the mechanisms mediating pain are unclear. In a murine model of neurogenic cystitis, Rudick and colleagues demonstrated that mast cells promote cystitis pain and bladder pathophysiology through the separable actions of histamine and TNF, respectively (Rudick et al, 2008). Therefore, pain is independent of pathology and inflammation, and histamine receptors may represent direct therapeutic targets for the pain of BPS and other chronic pain conditions.

Lynes and coworkers concluded that biopsy specimens are often not helpful in confirming the diagnosis (Lynes et al, 1990a). Although BPS patients in their study had a higher incidence and degree of denuded epithelium, ulceration, and submucosal inflammation, none of these findings was pathognomonic. In addition, these “typical” findings occurred only in BPS patients with pyuria or small bladder capacity. Epithelial and basement membrane thickness, submucosal edema, vascular ectasia, fibrosis, and detrusor muscle inflammation and fibrosis were not significantly different in the BPS and control patients.

Attempts to definitively diagnose BPS by electron microscopy have also been unsuccessful. Collan’s group, in the first such study (Collan et al, 1976), wrote that the similarity of the ultrastructure of epithelial cells in controls and IC patients makes it improbable that the disease process originates in the epithelium. Other investigators found no differences in the morphologic appearances of the glycocalyx and of urothelial cells in patients with IC when compared with controls (Dixon et al, 1986). Anderstrom and colleagues saw no surface characteristics specific for IC (Anderstrom et al, 1989), but believed that the mucin layer covering the urothelial cells seemed reduced in IC compared with controls, a fact disputed by Nickel in a very elegant paper (Nickel et al, 1993). Elbadawi and Light observed ultrastructural changes sufficiently distinctive to be diagnostic in specimens submitted for pathologic confirmation of nonulcerative IC (Elbadawi and Light, 1996). Marked edema of various tissue elements and cells appeared to be a common denominator of many observed changes. The wide-ranging discussion of the etiology of IC in his paper is fascinating, but the pathologic findings are potentially marred by the methodology, in that specimens were obtained after diagnostic hydrodistention (Elbadawi, 1997).

So what is the place of pathologic examination of tissue in BPS? Attempts to classify the painful bladder by the pathoanatomic criteria described by Holm-Bentzen (1989) are of questionable value. There is a group of patients with what she describes as *nonobstructive detrusor myopathy* (Holm-Bentzen et al, 1985). In her series, these patients with degenerative changes in the detrusor muscle often had residual urine, a history of urinary retention, and an absence of sensory urgency on cystometry with bladder capacities over 400 mL. Most of these signs would not be clinically confused with BPS. A similar English series (Christmas et al, 1996b), however, included patients who met NIDDK research criteria and associated detrusor myopathy with diminished detrusor compliance and ultimate bladder contracture.

The ICDB study worked backward from symptoms to pathology and concluded that certain symptoms are predictive of specific pathologic findings (Tomaszewski et al, 1999, 2001). Denson and colleagues analyzed forceps biopsy specimens from 65 females and 4 males with BPS (Denson et al, 2000). Ten percent of specimens showed vasodilatation or submucosal edema. Inflammation was absent in 30% of patients, and mild in another 41%. Cystoscopic changes did not correlate with degree of inflammation. Hanus and colleagues studied 84 biopsy specimens from 112 BPS

Animal Models

Until recently, lacking an easily available animal model of the naturally occurring disease, researchers have had to devise animal models to study isolated symptoms of BPS/IC, hoping to uncover the root causes of the symptomatology (Ruggieri et al, 1990). Although animal models can yield clues to cause, all theories must ultimately be tested in humans with the disease. Comparative and translational studies are required if the full potential of findings obtained with animal models is to be realized (Bjorling et al, 2011).

Bullock and associates reported a mouse model in which bladder inflammation could be induced by the injection of syngeneic bladder antigen (Bullock et al, 1992). The model demonstrated that a component in the Balb/cAN mouse is capable of inducing a bladder-specific, adoptively transferable, cell-mediated autoimmune response that exhibits many characteristics of clinical IC, but was difficult to reproduce (Klutke et al, 1997). In another mouse model, immunization of mice with recombinant mouse uroplakin II provoked an autoimmune response sufficient to induce an autoimmune cystitis (Altuntas et al, 2012). Injecting the Bartha strain of pseudorabies virus in the tail of mice causes female gender-specific pelvic pain (Rudick et al, 2012). In a pilot study, a mouse model using a synthetic APF intravesically has yielded histopathologic changes in the mouse similar to findings of IC/BPS patient biopsy specimens (Keay et al, 2012). Vascular endothelial growth factor (VEGF) instillation into the mouse bladder promotes a significant increase in peripheral nerve density with alterations in bladder function and visceral sensitivity (Malykhina et al, 2012).

In a guinea pig model, the instillation of a solution containing a protein to which the animal had been previously immunized resulted in bladder inflammation (Christensen et al, 1990; Kim et al, 1992), as did a rat model of allergic cystitis using a local challenge of ovalbumin in previously sensitized rats (Ahlwalia et al, 1998). Changes in the rat model were dependent on mast cell degranulation and activation of sensory C fibers. Induction of urinary symptoms after 7 days of repeated variate stress has been reported in a rat model (Merrill et al, 2013).

Ghoniem and coworkers studied four female African green monkeys challenged with intravesical acetone (Ghoniem et al, 1995). Not surprisingly, they exhibited symptoms of BPS. Rivas and associates performed similar experiments using dilute hydrochloric acid in a rat model (Rivas et al, 1997). A rat model for neurogenic cystitis using pseudorabies virus demonstrated that inflammatory changes in the spinal cord can result in dramatic, neurogenically mediated changes in the bladder (Doggweiler et al, 1998).

The problem with all these animal models relates to whether or not they mirror the human disease to any great extent. Buffington has described what appears to be a naturally occurring animal model of BPS/IC (Buffington, 2011) (Fig. 14-6). Two thirds of cats with lower urinary tract disease have sterile urine and no evidence of other urinary tract disorders (Kruger et al, 1991). A portion of these cats experience frequency and urgency of urination, pain, and bladder inflammation (Haupt, 1991). Glomerulations have been observed in the bladders of these animals. GP-51, a glycosaminoglycan (GAG) commonly found in the surface mucin covering the mucosa of the normal human bladder and decreased in IC, shows a decreased expression in cats with this symptom complex (Press et al, 1995), originally termed *feline urologic syndrome*. Bladder A δ afferents in these cats are more sensitive to pressure changes than are afferents in normal cats (Roppolo et al, 2005). They also demonstrate an increase in baseline nitric oxide production in smooth muscle and mucosal strips when compared with healthy cats, with evidence of altered mucosal barrier function (Birder et al, 2005).

Buffington now refers to this disorder as *feline interstitial cystitis* (FIC) (Buffington et al, 1999). It is associated with urinary urgency, frequency, and pain with sterile urine, bladder mastocytosis, increased histamine excretion, increased bladder permeability, decreased urinary GAG excretion (Buffington et al, 1996), and increased plasma norepinephrine concentrations (Buffington and Pacak, 2001).

Infection

Often, a diagnosis of BPS/IC is made only after a patient has been seen by a number of physicians and treated with antibiotics for presumed urinary tract infection without resolution of symptoms (Held et al, 1990). The symptom complex looks to the patient and physician like an infectious process (Porru et al, 2004). The epidemiology of urinary tract infection and its predominance in women mirror the BPS/IC data (Warren, 1994a). The acute to subacute onset in many patients has fascinated clinicians who often associate an insidious onset with a chronic condition such as BPS/IC.

Reverse logic led some to suspect that antibiotics may be instrumental in causing IC (Holm-Bentzen et al, 1990). Most patients have been treated with antibiotics once or several times before the diagnosis is made. Numerous antibiotics, primarily in the penicillin family, can induce cystitis (Bracis et al, 1977; Moller, 1978; Chudwin et al, 1979; Cook et al, 1979; Marx and Alpert, 1984), but no evidence has ever been documented that these antibiotics or the supposedly "surface active" nitrofurantoin or

Environmental modification intended to reduce perception of external threat has been found to be an effective approach to treatment of cats with FIC in both laboratory and clinical studies. (Courtesy Tony Buffington.)

tetracyclines have any involvement in pathogenesis (Ruggieri et al, 1987; Levin et al, 1988).

To determine whether there is an infectious cause of BPS, certain procedures are necessary (Warren, 1994b). Not just urine, but bladder epithelium as well must be cultured for appropriate microorganisms, including bacteria, viruses, and fungi. Because some organisms might be culturable yet fastidious, special culture techniques should be used. Because some organisms in urine or tissue might be viable but nonculturable, specific nonculture techniques for discovery and identification should be employed. Most important, the same procedures must be carried out in a control population.

Attempts to show an infectious cause go back to the dawn of the disease, but the case has never been a strong one (Duncan and Schaeffer, 1997). Hunner (1915) originally proposed that IC resulted from chronic bacterial infection of the bladder wall secondary to hematogenous dissemination. Harn proposed a relationship between IC and streptococcal and poststreptococcal inflammation (Harn et al, 1973). He produced a progressive chronic inflammation in rabbit bladders by injecting small numbers of *Streptococcus pyogenes* in the bladder wall. Studies of *Helicobacter pylori* have failed to demonstrate an association with IC (English et al, 1998; Agarwal and Dixon, 2003; Atug et al, 2004; Haq et al, 2004). Wilkins found bacteria in catheterized urine specimens and/or bladder biopsy samples in 12 of 20 patients with IC (Wilkins et al, 1989). However, 8 of the isolates were fastidious bacteria—*Gardnerella vaginalis* and *Lactobacillus* species—and no controls were included in the study. Polyomaviruses have been reported to cause a BPS/IC-like syndrome that responds to cidofovir treatment (Eisen et al, 2009). These viruses are excreted intermittently in the urine of healthy, asymptomatic adults, making diagnosis of a true infection problematic.

Negative studies far outnumber positive ones. Hanash and Pool performed viral, bacterial, and fungal studies on 30 IC patients and failed to substantiate an infectious cause (Hanash and Pool, 1970). Hedelin found only 3 of 19 IC patients to have urine cultures positive for *Ureaplasma urealyticum*, and indirect hemagglutination antibodies to *Mycoplasma hominis* to be no greater than in controls (Hedelin et al, 1983). Potts cultured *U. urealyticum* in 22 of 48 patients with “chronic urinary symptoms” and had great success in these patients (none of whom had established IC) with short courses of commonly prescribed antibiotics (Potts et al, 2000). Given the history of empirical antibiotics in the vast majority of IC patients, it is doubtful if this group represents even a small percentage of the IC-diagnosed population. Nevertheless, it illustrates that BPS/IC is a diagnosis of exclusion; urine culture is critical, and an empirical short course of antibiotics is certainly reasonable if the patient has not already been treated for presumed infection. Empirical doxycycline has been successfully used in this manner (Burkhard et al, 2004).

The development of highly sensitive, rapid, and specific molecular methods of identifying infectious agents by the direct detection of DNA or RNA sequences unique to a particular organism (Naber, 1994) resulted in a flurry of activity into the search for a responsible virus or microorganism. Hampson could find no evidence of mycobacterial involvement in 8 cases of BPS/IC with use of DNA probes (Hampson et al, 1993). Haarala confirmed an absence of bacterial DNA in the bladder of 11 BPS/IC patients with no documented history of urinary tract infection (Haarala et al, 1996). Hukkanen reported an absence of adenovirus and BK virus genomes in urinary bladder biopsy specimens of IC patients (Hukkanen et al, 1996). Domingue’s provocative finding of the presence of bacterial 16S rRNA genes in bladder biopsy specimens from 29% of IC patients but not from control bladders and his discovery of 0.22- μ m filterable forms in culture of biopsy tissue from 14 of 14 IC patients and 0 of 15 controls (Domingue et al, 1995) have never been confirmed or repeated.

A preliminary study found a statistically significant increase in urine polymerase chain reaction (PCR) to *Chlamydia pneumoniae* major outer membrane protein gene in patients with BPS/IC as compared with controls (Franke et al, 1999). Other studies have

shown that similar percentages of both IC and control patient populations have nonculturable bacteria in the bladder on the basis of PCR studies of bladder biopsy specimens (Heritz et al, 1997; Keay et al, 1998a). The spirochete *Borrelia burgdorferi* has been found in bladder biopsy specimens and urine of patients with Lyme disease and can cause frequency, urgency, and nocturia. DNA studies have failed to show a role for *Borrelia* in IC (Haarala et al, 2000). A study using high-throughput sequencing analysis of urine microbiota in BPS/IC patients compared with healthy females showed a reduced microbial diversity and richness accompanied by a higher abundance of the bacterial genus *Lactobacillus* in the BPS group (Siddiqui et al, 2012).

The role of infection in the pathogenesis of BPS/IC remains a mystery. At this time there are few data to support the role of an infectious cause, but investigators keep returning to an infectious theory. Insights into the mechanisms by which bacteria adhere, grow, and persist in association with host tissue and form intracellular pods capable of subverting host defense mechanisms and allowing replication within epithelial cells lay the foundation for a possible role of infection in initiating the BPS/IC pathologic cascade (Kau et al, 2005). The University of Maryland group proposed a model of BPS in which bladder epithelial damage such as that caused by bacterial cystitis may be the first step leading to a low-level inflammatory response (Keay and Warren, 1998). Domingue wrote, “It is logical to suggest that even if organisms are not causative agents, their presence may lead to immune and host-cell responses that could initiate or exacerbate an inflammatory state” (Domingue et al, 1997). In a case-control study, premenopausal women with a history of recurrent urinary tract infection had significantly greater urinary frequency, lower average voided volume, and a lower threshold of bladder sensitivity than controls (Arya et al, 2012).

If infection does play a role, it would be predicted that appropriate treatments to minimize microbial presence in the tissue would significantly improve the morbidity associated with BPS/IC. Durier’s incredible series (Durier, 1992) purporting to cure 27 out of 27 IC patients with the use of up to five sequential antibiotics covering the anaerobic spectrum has never been duplicated. Warren’s prospective, double-blind, placebo-controlled, randomized trial of 50 patients may well prove the end of long-term empirical antibiotic treatment in established BPS/IC (Warren et al, 2000). Eighteen weeks of placebo or antibiotics (sequential doxycycline, erythromycin, metronidazole, clindamycin, amoxicillin, and ciprofloxacin for 3 weeks each) were administered. Most patients guessed the arm to which they were assigned. Of the 25 patients in the active arm, 80% had new nonurinary symptoms perceived as side effects. There was minimal improvement in some patients associated with the active arm, but the conclusion that intensive antibiotics do not represent a major advance in therapy for IC seems well justified.

Although the concept that a urinary tract infection may trigger BPS in some patients is appealing (Elgavish et al, 1995; Elbadawi, 1997), it is unlikely that active infection is involved in the ongoing pathologic process or that antibiotics have a role to play in treatment.

Autoimmunity and Inflammation

Immune and neuroimmune mechanisms may have an important role in the pathogenesis of BPS/IC. Excessive release of sensory nerve neurotransmitters and mast cell inflammatory mediators is thought by some to be responsible for the development and propagation of symptoms (Luo, 2005). Inflammation results in altered nerve growth factor content of the bladder and morphologic changes in sensory and motor neurons innervating the bladder. Inhibition of nerve growth factor with a monoclonal antibody showed preliminary efficacy in amelioration of BPS symptoms in phase 2 studies (Evans et al, 2011). Neuroplasticity may be a possible explanation for the association of bladder inflammation with long-term symptoms and pain after inflammation has subsided (Dupont et al, 2001). Up to one third of BPS/IC patients may have an acute urinary tract infection that immediately precedes the onset

of chronic symptoms (Warren et al, 2008). However, abnormal differentiation in the urothelium with a loss of barrier function markers and altered differentiation markers may be independent and occur independently of inflammation (Hauser et al, 2008).

The role of inflammation may stem from inflammation originating in organs other than the bladder. Pain syndromes such as irritable bowel syndrome and BPS, which are associated with visceral hyperalgesia, are often comorbid with endometriosis and chronic pelvic pain. Tirlapur concluded that in women with chronic pelvic pain, the mean prevalence of BPS is 61%, the mean prevalence of endometriosis is 70%, and the two problems coexist in 48% of this population (Tirlapur et al, 2013a). One of the possible explanations for this phenomenon is viscerovisceral cross-sensitization, in which increased nociceptive input from an inflamed pelvic organ sensitizes neurons that receive convergent input to the same dorsal root ganglion from an unaffected visceral organ. Visceral sensory integration in the dorsal root ganglia has been demonstrated in a rodent model and may underlie the observed comorbidity of female pelvic pain syndromes (Li et al, 2008).

For many years the possibility that BPS may represent some type of autoimmune disorder has been considered. Narrowly defined, autoimmune diseases are clinical syndromes caused by the activation of T cells, B cells, or both, in the absence of an ongoing infection or other discernible cause (Davidson and Diamond, 2001). To establish a disease as autoimmune, three types of evidence can be marshaled: (1) direct evidence from transfer of pathogenic antibody or pathogenic T cells; (2) indirect evidence based on reproduction of the autoimmune disease in experimental animals; and (3) circumstantial evidence from clinical clues (Rose and Bona, 1993). Circumstantial evidence would include (1) association with other autoimmune diseases in the same individual or same family; (2) lymphocytic infiltration of a target organ; (3) statistical association with a particular major histocompatibility complex haplotype; and (4) favorable response to immunosuppression.

Circumstantial evidence by itself cannot define an autoimmune disease, and **at this point the case for autoimmunity in BPS/IC is far from clear**. Three different possibilities exist: (1) BPS is caused by a direct autoimmune attack on the bladder; (2) some of the autoimmune symptoms and pathology of BPS arise indirectly as a result of tissue destruction and inflammation from other causes; and (3) autoimmune phenomena in BPS patients are coincident and unrelated to the disease (Ochs, 1997).

Silk found bladder antibodies in 9 of 20 IC patients and none in 35 pathologic or normal control patients (Silk, 1970). Gordon found antibladder antibodies present in biopsy specimens from 6 of 8 IC patients and in 3 of 5 control patients (Gordon et al, 1973). No control patient demonstrated antibodies in the muscle, whereas 3 of 5 IC patients with muscle in the biopsy specimen did. Jokinen looked at sera from 33 IC patients and found 28 with an antinuclear antibody (ANA) titer of 1:10 or greater, but no bladder-specific antibodies were detected with immunofluorescence. There was poor correlation between ANA titers and symptom severity (Jokinen et al, 1972a). He noted that elevated antibody titers against cell nuclei and crude kidney homogenate decreased within 12 months after cystectomy in 3 IC patients (Jokinen et al, 1973). All of this provided hints that BPS/IC could fall into the autoimmune group of diseases.

Oravisto summarized the world literature on this idea in 1980, concluding that the chronic course of disease, the absence of infection, the pathologic findings, the occurrence of ANAs, and the reported responses to steroids at that time provided strong circumstantial evidence of autoimmunity (Oravisto, 1980). He discounted the paucity of activated lymphocytes, which speaks against an autoimmune process. Studies on autoantibodies in BPS/IC have shown that these mainly consist of ANAs (Jokinen et al, 1972a), similar to the autoantibody profiles in some systemic diseases such as SS, well known to be of autoimmune origin (Tan, 1989; Leppilähti et al, 2003). Mattila presented evidence of immune deposits in the bladder vascular walls in 33 of 47 BPS/IC patients (Mattila, 1982). Studying sera from 41 patients with IC, he concluded that the classical pathway activation of the complement

system was involved, supporting the possibility that a chronic local immunologic process was indeed occurring (Mattila et al, 1983). The autoantibodies tested were found to be directed against cytoskeletal intermediate filaments. As the autoantibodies have to gain access to intracellular structures to cause *in vivo* deposits, primary tissue injury of unknown cause has to be postulated (Mattila and Linder, 1984).

Anderson and colleagues studied 26 patients with BPS/IC and compared them with a control group of similar age and sex with other urologic complaints (Anderson et al, 1989). They performed a standard autoimmune profile and looked for specific antibodies to normal human bladder in the serum. Sixty-five percent of IC patients and 36% of controls demonstrated non-organ-specific antibodies; 40% of IC patients had ANAs; and 75% of IC patients and 40% of controls had antibladder antibodies present in the serum. There was no increase in immunoglobulin deposition in the bladder epithelium in IC patients versus controls. Although IC patients demonstrated a nonspecific increase in antibody formation, this was not significantly different from a similar group of other urologic patients. The lack of specificity indicates the immunologic findings are likely secondary to inflammation rather than a primary cause.

In a study looking for active immune cellular deposition in BPS/IC patients, no statistically significant difference between controls and IC patients was identified (Harrington et al, 1990). In contrast, the ulcerative BPS group had focal sheets of plasma cells, aggregates of T cells, B cell nodules, a decreased or normal helper-to-suppressor cell ratio, and suppressor cytotoxic cells in germinal centers. Flow cytometry analysis of peripheral blood lymphocyte subsets showed increased numbers of secretory Ig-positive B cells and activated lymphocytes in the non-Hunner group, and increased numbers of secretory Ig-positive cells and activated lymphocytes in the Hunner group. These results may suggest a partial role for an immune mechanism in IC. Gamper and colleagues found elevated urinary antibody concentrations in patients with Hunner lesions (Gamper et al, 2013). Erickson and coworkers have noted a major difference in inflammatory cell types as well as clinical features in BPS/IC patients with severe inflammation, suggesting two different patient groups with two different underlying pathophysiologies (Erickson et al, 1997a).

Hanno and colleagues found CD4 cell predominance in all layers of the bladder in BPS/IC patients (Hanno et al, 1990). Christmas (1994) reported increased numbers of CD4⁺ and CD8⁺ T cells in bladder biopsy specimens from patients with IC and bacterial cystitis as compared with controls. These T cells were present in the urothelium and submucosa but not in the detrusor. Control bladder tissue demonstrated only CD8 cells in the urothelium and both CD4⁺ and CD8⁺ cells in the submucosa. The number of plasma cells was significantly greater in IC patients than in normal controls and controls with bacterial cystitis.

MacDermott and colleagues found a normal distribution of peripheral blood lymphocytes in IC patients, a finding not supportive of an autoimmune mechanism in the disease (MacDermott et al, 1991b). The lamina propria showed a predominance of CD4 lymphocytes (helper T cells) over CD8 cells in both IC and other cystitis patients. The same pattern was seen in the epithelium of patients with bacterial or mechanical cystitis, but patients with IC had a predominance of CD8 lymphocytes in the urothelium—identical to controls. The findings suggest that the urothelium is not involved in the inflammatory reaction, as is the lamina propria, making the urothelium an unlikely source for the initiating factor.

Miller and coworkers investigated the function of peripheral blood lymphocytes from nonulcerative IC patients, testing the proliferative response and cytokine production of T cells to nonspecific mitogenic stimulation and the proliferative response of T cells to urine components (Miller et al, 1992). Proliferation and cytokine production after mitogen stimulation were the same for controls and BPS/IC patients. Moreover, no immunologic response to IC urine by autologous peripheral blood lymphocytes *in vitro* assays was observed. These findings cast doubt on theories suggesting that IC is an autoimmune disease.

Numerous inflammatory mediators have been studied with regard to their relation to BPS (Elgebal et al, 1992; Felsen et al, 1994; Lotz et al, 1994; Steinert et al, 1994; Zuraw et al, 1994). There is a significant elevation of cytokines in BPS/IC bladder tissue when compared with controls (Corcoran et al, 2013) and an increase in urinary nerve growth factor (Liu and Kuo, 2012). The overexpression of genes related to immune and inflammatory responses, including T helper type 1-related chemokines and cytokines such as CXCR3 binding chemokines, may produce potential biomarkers of the disease (Ogawa et al, 2010). Urine sediment may be a substrate for gene expression analysis (Blalock et al, 2012).

Patients with BPS/IC exhibit varying degrees of inflammation that can separate them into clusters (Tomaszewski et al, 2001; Green et al, 2004). Bladder inflammation in IC is categorized by elevated urinary interleukin-6 (Erickson et al, 1997a) and activation of the kallikrein-kinin system (Rosamilia et al, 1999b). The absence of urinary interleukin-1 β in IC argues against an immunologic or autoimmune cause of the disorder (Martins et al, 1994). Neurogenic inflammation may play a role in the cause, as long-term exposure of afferent nerve terminals to inflammatory mediators can alter ion channels and result in bladder hyperalgesia (Buffington and Wolfe, 1998; Yoshimura and de Groat, 1999). Substance P itself does not seem to be the single initiator of inflammation in the bladder, and its blockade does not protect the bladder in animal models from inflammatory responses (Luber-Narod et al, 1997). Urinary nitric oxide synthase (NOS) activity is known to be elevated in patients with urinary infection and is thought to play a role in the bladder's response to infection and in the inflammatory process that follows infection. The finding that urinary NOS activity is decreased in BPS/IC patients has puzzled researchers but could explain the reduction in functional bladder capacity associated with the disorder (Smith and Christmas, 1996; Foster et al, 1997). However, patients with Hunner lesions have high levels of nitric oxide in the bladder. The production of nitric oxide in this entity may occur in different tissue compartments, because there is strong immunoreactivity for both inducible nitric oxide synthase (iNOS) in the urothelium and within the inflammatory infiltrates in the lamina propria of these patients (Logadottir et al, 2013).

Urothelial cell activation in IC may result in aberrant immune responses and immune activation within the bladder wall (Liebert et al, 1993) that could relate to pathogenesis of the disease but might not reflect the initiating cause (Ochs et al, 1994). It has been proposed that inflammatory and/or immune responses in IC could be exacerbated by persistent activation of nuclear factor- κ B (NF- κ B) (Abdel-Mageed and Choniem, 1998; Abdel-Mageed, 2003). Angiogenic factors such as platelet-derived endothelial cell growth factor/thymidine phosphorylase and transforming growth factor- β may be involved in the inflammatory process to induce painful symptoms in patients with IC or bladder carcinoma (Ueda et al, 2002).

The exact role of autoimmunity in IC remains controversial (Ochs, 1997). Suplatast tosilate, an immunoregulator, has shown efficacy in a small, uncontrolled IC study in which improvements in symptoms and bladder capacity were correlated with changes in autoimmune parameters (Ueda et al, 2000). Although the immune system remains a target for therapy, no clear indication of a primary role for autoimmunity as the cause of IC has been observed (Liebert and Sant, 1997).

Mast Cell Involvement

Although mast cells are thought of primarily in the context of allergic disorders and certain acute inflammatory responses, these cells have also been implicated in biologic responses as diverse as angiogenesis and wound healing, bone remodeling, peptic ulcer disease, atherosclerosis, and reactions to neoplasms (Galli, 1993). Mast cells remain one of the most enigmatic cells in the body. They secrete significant amounts of numerous proinflammatory mediators that contribute to a number of chronic inflammatory conditions, including stress-induced intestinal ulceration, rheumatoid arthritis, scleroderma, and Crohn disease. They have been described even among the lowest order of animals, having been

KEY POINTS: AUTOIMMUNITY AND INFLAMMATION

- Neuroplasticity may be a possible explanation for the association of bladder inflammation with long-term symptoms and pain after inflammation has subsided.
- Abnormal differentiation in the urothelium with a loss of barrier markers and altered differentiation markers may be independent and may occur independently of inflammation.
- Visceral sensory integration may result in inflammation originating in organs other than the bladder causing symptoms identified with BPS.

discovered in the frog mesentery over 100 years ago. Their *raison d'être* may be the initiation and coordination of the host's inflammatory and immune responses against microbial pathogens (Abraham and Malaviya, 1997). They have been implicated in a range of neuroinflammatory diseases, especially those worsened by stress (Theoharides, 2004; Theoharides and Cochrane, 2004). These include multiple sclerosis, migraines, inflammatory arthritis, atopic dermatitis, coronary inflammation, irritable bowel syndrome, and BPS/IC. They may be activated through their Fc receptors by immunoglobulins other than IgE, as well as by anaphylatoxins, neuropeptides, and cytokines, to secrete mediators selectively without overt degranulation.

Mast cells have frequently been reported to be associated with IC, both as a pathogenetic mechanism and as a pathognomonic marker (Simmons, 1961; Bhone et al, 1962; Smith and Dehner, 1972; Larsen et al, 1982; Hofmeister et al, 1997). The association of bladder mastocytosis, IC, and irritable bowel syndrome (Pang et al, 1996) and chronic urticaria (Sant et al, 1997) is intriguing. Evidence of their importance is mounting, suggesting that they may serve as the final common pathway through which the symptomatic condition is expressed. Mast cells produce, among other compounds, histamine. Histamine release in tissue causes pain, hyperemia, and fibrosis, all notable features of IC.

Simmons was the first to suggest mast cells as a cause of IC (Simmons, 1961). Contribution of mast cells to the cellular infiltrate in IC (Fig. 14-7) has been shown to vary from about 20% in nonulcer IC patients to 65% in patients with ulceration (Sant et al, 1988; Enerback et al, 1989). Mast cells participate in allergic reactions (hypersensitivity type I) during which IgE antibody is synthesized in response to specific antigens. IgE binds to mast cell receptors, and antigen binds to the IgE, leading to degranulation (Lagunoff et al, 1983). Other triggers of mast cell secretion include acetylcholine, anaphylatoxins, cationic peptides such as substance

Figure 14-7. Giemsa stain shows detrusor mastocytosis and nerve hypertrophy in bladder pain syndrome (original magnification $\times 400$). (Courtesy John Tomaszewski, Hospital of the University of Pennsylvania, Department of Pathology).

P, chemicals, contrast, cytokines, opioids, antihistamines, exercise, hormones, viruses, and bacterial toxins (Sant and Theoharides, 1994). Mast cells promote infiltration of neutrophils, T and B lymphocytes, monocytes, and eosinophils. T lymphocytes secrete substances capable of activating mast cells, thus perpetuating the cycle of inflammation (Kaplan et al, 1985).

Since the presence of mast cells within the bladder wall was first recognized (Simmons and Bunce, 1958), numerous investigators have tried to determine whether there is an increase in the number of mast cells in the bladder of patients with IC, or differences in their location or functional state (Larsen et al, 1982; Kastrup et al, 1983; Fall et al, 1987; Feltis et al, 1987; Lynes et al, 1987; Christmas and Rode, 1991). An increase in urothelial mast cells appears to be part of the generalized inflammatory cell reaction regardless of cause, and not a specific feature of IC, whereas the presence of increased numbers of mast cells in the detrusor is more specific for IC. However, one study did report detrusor mastocytosis in 64% of IC patients and 80% of a control group with other urologic disease, with no statistically significant difference between the mean number of detrusor mast cells in the two groups (Hanno et al, 1990).

Aldenberg reported that mast cells are found predominantly in the detrusor muscle in patients with classic IC (Aldenberg et al, 1986), but there is also a secondary population of mast cells in the lamina propria and the bladder epithelium, with staining characteristics distinct from those in the detrusor. None of these epithelial mast cells were found in controls. These findings were interpreted to indicate a transepithelial migration of mast cells in patients with IC. This second population of mast cells does not appear to be involved in the nonulcer type of IC (Aldenberg et al, 1989). This mucosal population of mast cells can also differ from the mast cells found in deeper tissues in physiologic responses and release of secretory products (Sant, 1991). The “mucosal mast cells” are susceptible to aldehyde fixation and require special fixation and staining techniques for proper demonstration. Detrusor mast cells are not susceptible to fixation techniques. Recent studies have shown that although all human mast cells contain the proteinase tryptase, there is a population of mast cells that also contain the proteinase chymase. The mast cell expansion in IC involves both types (Yamada et al, 2000). Mast cell activation is far more pronounced in the ulcerative form, which in addition displays prominent inflammation, in contrast to nonulcer IC, in which it is sparse. Thus, the basic pathologic processes may differ (Peeker et al, 2000b). Because activated mast cells lose their histologically identifiable granules once degranulation has occurred, estimates of mast cell density using standard histologic techniques may underestimate mast cell numbers (Sant and Theoharides, 1994).

Electron microscopy has confirmed that mast cells in IC are more likely to be degranulated or activated than those found in other conditions (Larsen et al, 1982; Theoharides and Sant, 1991; Theoharides et al, 1995). In at least a subpopulation of IC patients, this may be explained by increased stimulation of mast cells by stem cell factor (Pang et al, 1998). A chronic exposure of detrusor muscle to histamine in IC patients is suggested by the finding that there is an impairment of the direct contractile response to histamine in detrusor muscle affected by IC in comparison with control detrusor, suggesting a receptor desensitization (Palea et al, 1993). The clinical relationship between an increased number of mast cells and symptoms of IC has not been definitively established. Some studies have found no correlation (Holm-Bentzen et al, 1987a; Lynes et al, 1987; Dondore et al, 1996). Although mast cell infiltration in intestinal segments used for augmentation has been associated with pain and failure of the procedure (Kisman et al, 1991), other researchers have shown that mast cell infiltration in intestine used in the urinary tract is the norm and not pathologic (MacDermott et al, 1990).

Many of the substances that have been shown to induce mast cell secretion are released from neurons that innervate the organ containing the mast cells (Christmas et al, 1990). The capsaicin-sensitive sensory neurons that innervate the bladder are thought to have a dual “sensory-efferent” function, in which an axon reflex-induced release of neuropeptides results in local inflammation

(Foreman, 1987; Barbanti et al, 1993). Hand (1949) reported an increase in the submucosal nerve density in IC, a phenomenon confirmed by Christmas and colleagues (1990), who showed an increase in nerve fiber proliferation in IC but not in patients with bacterial or lupus cystitis. Increased innervation by nerves releasing substances affecting mast cells could lead to increased mast cell secretion. Among these substances is acetylcholine. Mast cells can be stimulated by cholinergic agonists to secrete serotonin (Theoharides and Sant, 1991). Substance P-containing fibers have been found to be increased in bladders from IC patients and are found adjacent to mast cells (Pang et al, 1995b). In mice, mast cells modulate the inflammatory response of the bladder to substance P and to *Escherichia coli* lipopolysaccharide (Bjorling et al, 1999).

An increase in adrenergic but not cholinergic nerves in IC patients as compared with controls has been reported (Hohenfellner et al, 1992). Hohenfellner and colleagues also found increased numbers of neurons staining for vasoactive intestinal polypeptide and neuropeptide Y (NPY), both of which are associated with sympathetic nerves. Studies in rats have revealed that psychological stress can activate bladder mast cells via the action of sensory neuropeptides (Spanos et al, 1997; Alexacos et al, 1999). Diurnal cortisol variations have been associated with symptom levels in BPS/IC (Lutgendorf et al, 2002), and the mast cell may represent a pathway for stress to be reflected in bladder symptomatology.

Mast cells can alter their environment by regulating tissue gene expression (Saban et al, 2001). The finding of increased synthesis of urinary leukotriene E₄ in patients with IC and detrusor mastocytosis when compared with healthy controls suggests that cysteinyl-containing leukotrienes are involved in the inflammatory reaction observed in the urinary bladder of patients with IC and may be produced from tissue mast cells in the bladder wall, or macrophages (Bouchelouche et al, 2001a).

Could mast cell products be useful in diagnosing BPS/IC? They are not specific for BPS/IC and are increased in bladder carcinoma (Serel et al, 2004). Elevated histamine levels have been found in bladder biopsy specimens from IC patients (Kastrup et al, 1983; Lynes et al, 1987; Enerback et al, 1989) as well as from bladder washings (Lundeberg et al, 1993). Holm-Bentzen reported a significantly elevated urinary excretion of 1,4-methylimidazole acetic acid, the major metabolite of histamine (Holm-Bentzen et al, 1987c). Others have found no differences between IC and controls in random spot tests of urinary histamine (Yun et al, 1992). Levels were elevated after hydrodistention in IC patients but not in controls—a possible consequence of hydrodistention and resultant mast cell degranulation. El Mansoury found increased methylhistamine, a histamine metabolite, in spot and 24-hour urine samples from IC patients as compared with controls (El Mansoury et al, 1994). Although such an increase could still be interpreted as indicating a systemic rather than a bladder syndrome, subsequent findings of elevated mast cell tryptase in the urine of IC patients could come only from the bladder (Boucher et al, 1995). Erickson and colleagues reported that urine methylhistamine is not useful as an objective marker of response to bladder distention or as a predictor of response to distention or as a substitute for bladder biopsy to determine mast cell counts (Erickson et al, 2004).

The realization that mast cells are associated with the syndrome of BPS by no means diminishes the other multiple theories of causation. The poor clinical results with antihistamine therapy would argue against their being a primary factor. Their very presence could be related to injury from any of the proposed etiologic theories, and degranulation could likewise reflect a final common pathway resulting in pain and frequency from multiple causes. Rickard and Lagunoff proposed, based on results with mast cell granules and epithelial cells in tissue culture, that mast cells could contribute to failure of epithelialization of the bladder surface by two potential mechanisms after injury: (1) inhibition of epithelial cell replication, and (2) interference with epithelial cell spreading, thus resulting in the “leaky epithelium” found in some patients (Rickard and Lagunoff, 1995). Mast cell activation has been correlated significantly with the apoptotic cell number in BPS bladder tissue (Shie and Kuo, 2011). Mast cells may actually be the mediator through which

female hormones play a role, accounting for the 10:1 female-to-male preponderance of the disease (Vliagoftis et al, 1992; Pang et al, 1995a; Patra et al, 1995; Bjorling and Wang, 2001). Estradiol augments the secretion of mast cell histamine in response to substance P. It has been proposed that the symptoms of BPS/IC may depend on an imbalance between the relative number of estrogen receptors and progesterone receptors on bladder mast cells (Letourneau et al, 1996).

To summarize, much important IC research has centered on the mast cell. These cells are strategically localized in the urinary bladder close to blood vessels, lymphatics, nerves, and detrusor smooth muscle (Saban et al, 1997). **Studies to date strongly suggest that BPS is a syndrome with neural, immune, and endocrine components in which activated mast cells play a central, although not primary, pathogenetic role in many patients** (Elbadawi and Light, 1996; Filippou et al, 1999). Studies in a mast cell-deficient mouse model demonstrate that mast cells promote cystitis pain and bladder pathophysiology through the separable actions of histamine and tumor necrosis factor (TNF), respectively, suggesting that pain is independent of pathology and inflammation, and histamine receptors may represent direct therapeutic targets for pain in BPS/IC (Rudick et al, 2008).

KEY POINTS: MAST CELLS AND HISTAMINE

- Mast cells may be a pathognomonic marker for BPS and also represent a pathogenetic mechanism of the syndrome. They could serve as a final common pathway through which the symptomatic condition is expressed.
- Histamine, produced by mast cells, may cause pain, hyperemia, and fibrosis, all notable features of BPS.

Bladder Glycosaminoglycan Layer and Epithelial Permeability

Until the early 1970s, most investigators thought that the major barrier to free flow of urinary constituents was at the level of the epithelial cells. Tight junctions between urothelial cells, specialized “umbrella cells” lining the surface, and direct bactericidal activity of the vesical mucosa were thought capable of defense of the internal milieu from bacteria, molecules, and ions in the urine (Ratliff et al, 1994). Staehelin and colleagues proposed that lipid and other hydrophobically bonded materials were important in any barrier to permeability in the luminal membrane because permeants leaked through the interplaque regions if the particles alone limited transport (Staehelin et al, 1972). It has been shown that inflammation of the underlying muscle and lamina propria can disrupt the bladder permeability barrier by damaging tight junctions and apical membranes and causing sloughing of epithelial cells. Leakage of urinary constituents through the damaged epithelium may then exacerbate the inflammation in the underlying tissues (Lavelle et al, 1998, 2000).

It was Parsons who hypothesized and popularized the concept that IC in a subset of patients is the result of some defect in the epithelial permeability barrier of the bladder surface GAGs (Parsons and Hurst, 1990). The major classes of GAGs include hyaluronic acid, heparin sulfate, heparin, chondroitin 4-sulfate and chondroitin 6-sulfate, dermatan sulfate, and keratan sulfate. These carbohydrate chains, coupled to protein cores, produce a diverse class of macromolecules, the proteoglycans (Trelstad, 1985). GAGs exist as a continuous layer on the bladder urothelium (Dixon et al, 1986; Cornish et al, 1990). Except heparin, all the other types of GAGs have been found on the bladder surface (Ruoslahti, 1988). **The GAG layer functions as a permeability and antiadherence barrier.** When impaired, its functions can be duplicated by exogenous GAG (Hanno et al, 1978a, 1978b). In the absence of this protective layer in the urinary bladder, its susceptibility to infection

would increase, and the production of nitric oxide in the urothelial cells and of substance P in the intraepithelial afferent C-fiber terminals increases. Consequently, the permeability of both the urothelium and the blood vessels in the mucous membrane increases, and the blood flow slows as a result of vasodilatation (Hohlbrugger, 1999).

Parsons and Hurst reported a lower excretion of urinary uronic acid and GAGs in IC patients than in normal volunteers and hypothesized that a leaky transitional epithelium might be absorbing these substances to its surface (Parsons and Hurst, 1990). The data are interesting in that one might expect urinary GAG to increase with injury to the bladder and decrease with resolution (Uehling et al, 1988). Buzzega and coworkers noted a significant increase in total urinary hexosamines and in particular in glucosamine belonging to urinary heparin sulfate in BPS patients compared with controls (Buzzega et al, 2012). The San Diego group (Lilly and Parsons, 1990; Parsons et al, 1990;) went on to show experimentally that one can damage the GAG layer with protamine sulfate with resultant back-diffusion of urea through the bladder lumen, and that this urea loss can be prevented with a bladder instillation of exogenous GAG (heparin). By placing a solution of concentrated urea into the bladder of IC patients and measuring absorption versus controls, Parsons found support for his theory in patients with IC (Parsons et al, 1991). The rationale of the epithelial permeability school has been nicely summarized in four publications (Parsons, 1993, 1994; Hurst et al, 1997; Hohlbrugger and Riedl, 2000) and provides a comprehensive, if somewhat imperfect, theory of the disorder.

Support for an epithelial abnormality from a different perspective has come from Bushman, who found aneuploid DNA profiles on barbotage specimens from IC patients that may signal an underlying abnormality of the epithelial cell population in some patients with IC (Bushman et al, 1994). Wilson and colleagues identified a loss of type IV collagen in the urothelial basement membrane in 5 of 11 IC patients (Wilson et al, 1995). Hurst's group studied bladder biopsy specimens of IC patients and controls and concluded that there is a deficit of bladder luminal and basal proteoglycans associated with the disorder. The basal abnormality may reflect an altered urothelial differentiation program (Hurst et al, 1996). In a later study, IC bladder biopsy specimens showed abnormalities in 24 of 27 patients when examined by immunohistochemical assessment of E-cadherin, ZO-1, uroplakin, and chondroitin sulfate (Slobodov et al, 2004). Erickson and coworkers measured a glycoprotein (epitactin) in the urine of IC patients and found a decrease compared with a control population, although a significant overlap was detected (Erickson et al, 1996). Buffington and Woodworth gave 6 IC patients and 6 controls oral fluorescein dye. IC patients had higher levels of fluorescein in their plasma and lower urinary excretion of the dye, suggesting altered membrane permeability and increased fluorescein reabsorption in the bladder wall of IC patients (Buffington and Woodworth, 1997). Erickson and colleagues compared urinary levels of hyaluronic acid in IC patients and controls, reporting higher urinary hyaluronic acid in the patient group, possibly accounted for by leakage of this GAG across the epithelium (Erickson et al, 1998).

In FIC, the only naturally occurring animal model of the disorder, the urothelium has been shown to have decreased transepithelial resistance and increased water and urea permeability compared with controls in response to hydrodistention (Lavelle et al, 2000). This indicates that barrier function is compromised, which could lead to the sensitization of sensory nerves by irritants from urine crossing into the muscle layer. Bladder strip studies have shown that FIC bladders have significantly more spontaneous Ca^{2+} transients in the mucosal layer than control bladders. Coupled with increased sensitivity of muscarinic receptors in the mucosal layer, these bladders may manifest enhanced smooth muscle spontaneous contractions. This finding could play a contribution in the symptoms of BPS/IC (Ikeda et al, 2009). In fact, human cell culture studies comparing BPS/IC and normal bladder urothelial cells have shown greater sensitivity of IC bladder urothelial cells to carbachol, suggesting that BPS/IC pathobiology may also include alterations in

muscarinic signaling (Gupta et al, 2009). Neuhaus and colleagues have shown significantly upregulated M₂ (muscarinic), P2X₁ and P2X₂ (purinergic), and H₁ and H₂ (histaminergic) receptors in the tissue of BPS patients (Neuhaus et al, 2011).

Further data for an abnormal surface mucin came from Moskowitz and colleagues, who studied biopsy specimens from 23 IC patients with regard to the presence of a glycoprotein component of the surface mucin referred to as GP1 and compared the results with 11 normal controls. Qualitative GP1 changes in a majority of IC patients were identified. GP1 reactivity was noted in all controls but was absent in 35% of IC patients and diminished in 61% (Moskowitz et al, 1994). This study may provide evidence of an abnormal bladder urothelium, but the effects of bladder distention in the IC group are unknown and may have contributed to the results. There were no pathologic controls used, and no attempt was made to correlate GP1 reactivity with IC symptoms (Messing, 1994). Castration in female rabbits is associated with bladder mucosal changes resulting in increased mucosal permeability (Parekh et al, 2004). Birder and colleagues have shown that FIC results in increased baseline production of nitric oxide as a result of iNOS (Birder et al, 2005). These changes in transmitter release may have a role in altering mucosal barrier properties.

VEGF plays a key role in bladder inflammation and is closely associated with the vascular alterations observed in patients with BPS/IC. VEGF and coreceptors (neuropilins [NRPs]) are strongly expressed in human bladder urothelium. NRP-2 and VEGFR-1 are significantly downregulated in IC when compared with control subjects (Saban et al, 2008). GAG modification of NRPs plays a critical role in modulating VEGF/NRP signaling (Shintani et al, 2006), suggesting another possible mechanism whereby a GAG deficiency could act, by interfering with the functionality of this signaling system.

Some have cited the “potassium sensitivity test” as providing strong evidence for a population with mucosal leak (Parsons et al, 1994b). Parsons placed water or 0.4-M potassium chloride (KCl) intravesically into normal volunteers and IC patients. Water did not provoke pain in either group, but KCl provoked the symptom in 4.5% of normal subjects and 70% of IC patients. Symptomatic responses were reduced in patients on heparinoid therapy. Similar findings occur in patients with radiation cystitis (100%) (Parsons et al, 1994b), urinary infection (100%) (Parsons et al, 1998), detrusor instability (25%) (Parsons et al, 1998), and “urethral syndrome” (55%) (Parsons et al, 2001b) and in more than 80% of women with endometriosis, vulvodynia, and pelvic pain (Parsons et al, 2001a, 2002b). Up to 33% of unselected Turkish women may test positive (Sahinkanat et al, 2008). Eighty-four percent of men with prostatitis also have a positive test result (Parsons and Albo, 2002). The poor specificity of the potassium test suggests that it does not provide unequivocal evidence of a permeability dysfunction. Because it is known that the normal bladder epithelium can never be absolutely tight and that there is always some leak, however small (Hohlbrugger and Sant, 1997), it is conceivable that the findings of pain with KCl are related to a hypersensitivity of the sensory nerves in this condition rather than to pathologic epithelial permeability, at least in some patients. In fact, KCl administered intravesically to cats with FIC seems to *inhibit* afferent firing of peripheral A δ fibers. Heightened sensitivity of afferent nerve fibers can explain KCl results without necessarily evoking increased permeability (Lutgendorf and Kreder, 2005; Roppolo et al, 2005). Intravesical administration of KCl has since been proposed as a diagnostic test for IC (Parsons et al, 1998) (see later).

How central abnormal epithelial permeability is to IC is, however, by no means clear. Tamm-Horsfall protein (THP), a high-molecular-weight glycoprotein synthesized exclusively by the ascending loop of Henle and the distal tubule of the kidney, has been studied as a potential marker of urothelial permeability. Fowler provided graphic data that the urothelium might be leaky in IC. With immunohistochemical techniques, his group assayed the bladder biopsy specimens of 14 IC patients and 10 normal controls for intraurothelial THP to assess indirectly the *in vivo* permeability of the urothelium. Eight pathologic controls were also assessed. Ten of 14 IC patients

versus 1 of 18 controls demonstrated intraurothelial THP (Fowler et al, 1988). Serum THP autoantibody is higher in BPS/IC patients versus controls (Neal et al, 1991). It is known that excretion rates of THP vary widely, even in repeat samples taken from the same individual (Reinhart et al, 1990). Subsequent studies in IC have failed to show differences in the presence of intraurothelial THP in the IC population versus controls, and in antibody reactivity to THP (Stone et al, 1992; Stein et al, 1993). Parsons reported that the THP protein is qualitatively different in patients with IC than in controls, even if the urinary concentration of the protein is the same (Parsons et al, 2007, 2011; Argade et al, 2013). Bade and coworkers failed to find THP in bladder tissue from 10 IC patients (Bade et al, 1996). Others have suggested that when THP is seen in bladder tissue, it is an incidental finding of no clinical significance. The finding of intraurothelial THP has not been shown to be a harbinger of IC or any other bladder disorder (Truong et al, 1994).

Finally, we must look at a body of literature that has failed to find GAG abnormality or hyperpermeability. Ultrastructural, biochemical, and functional studies of bladder GAG have not supported this theory (Collan et al, 1976; Dixon et al, 1986; Johansson and Fall, 1990; Ruggieri et al, 1991). Nickel's group reported on use of sophisticated electron microscopy with a specific antimucus, antisera stabilization technique to study the ultrastructural morphologic appearance of the GAG layer (Nickel et al, 1993). No significant difference in the morphologic appearance of the mucus or GAG layer was noted in IC versus controls. Urinary chondroitin sulfates, heparan sulfate, and total sulfated GAGs normalized to creatinine are not altered in IC (Erickson et al, 1997b). Although an increased ratio of total GAGs to sulfated GAGs in IC may indicate an altered GAG layer, whether it reflects a cause or is a result of the primary pathologic process(s) is unknown (Wei et al, 2000). That leaves one to postulate an as-yet-unknown functional abnormality, rather than GAG deficiency, to account for any increase in permeability.

Chelsky and coworkers measured bladder permeability in IC using direct measurement by transvesical absorption of technetium-99m diethylenetriaminepentaacetic acid (DTPA). Although some IC patients had a more permeable bladder than others, the same was true for normal volunteers. Increased permeability in the IC group could not be demonstrated. However, 3 IC patients had marked absorption of DTPA and may represent a subpopulation of patients with increased epithelial permeability (Chelsky et al, 1994). Intravesical instillation of 10% and 20% ethanol in rabbits was reported to be a reliable quantitative measure of bladder hyperpermeability by the San Diego group (Monga et al, 2001), and subsequently failed to demonstrate bladder permeability in humans with IC (Gordon et al, 2003).

Overall, it does seem that there is a population of BPS/IC patients with increased epithelial permeability, but the issue is far from closed. Increased mucosal permeability is nonspecific and a consequence of bladder inflammation, and also occurs with cyclophosphamide-induced bladder injury, bacterial infection, and cystitis following intravesical challenge with antigen after sensitization (Engelmann et al, 1982; Kim et al, 1992). It may also be a consequence of aging itself (Jacob et al, 1978). Whether this represents a primary cause of IC or merely reflects the result of an as-yet-unidentified source of inflammation is unclear. Treatments that tend to damage GAG, including transurethral resection and laser of ulcerated areas, bladder distention, silver nitrate administration, Clorapactin administration, and administration of the organic solvent dimethyl sulfoxide (DMSO) have all been used with varying results to treat IC.

One does not need increased permeability of the mucosa as a foundation for the many potential causes or contributing factors to BPS/IC. Enhanced adenosine triphosphate (ATP) release from the urothelium of patients with BPS/IC has been described (Kumar et al, 2007). This non-neuronal ATP may act as a sensory neurotransmitter. Increased purinergic activity may thus lead to a condition in which the bladder is oversensitive to distention.

Increased permeability and epithelial dysfunction must be only a part of the story.

KEY POINTS: EPITHELIAL PERMEABILITY

- There is a population of BPS patients with increased epithelial permeability.
- Increased mucosal permeability is nonspecific and a consequence of bladder inflammation. It also occurs with cyclophosphamide-induced bladder injury, bacterial infection, and cystitis following intravesical challenge with antigen after sensitization.
- Whether this represents a primary cause of BPS or merely reflects the result of an as-yet-unidentified source of inflammation is unclear.

Inhibition of Uroepithelial Cell Proliferation: Antiproliferative Factor

The finding that cells from the bladder lining of normal controls grow significantly more rapidly in culture than cells from BPS/IC patients (Keay et al, 1996) led Keay and associates at the University of Maryland to the discovery of an APF produced by the urothelium of IC patients. Normal bladder cells were cultured in the presence of urine from patients with IC, asymptomatic controls, bacterial cystitis, and vulvovaginitis. Only urine from IC patients inhibited bladder cell proliferation (Keay et al, 1998b). The presence of APF was found to be a sensitive and specific biomarker for IC patients who met NIDDK criteria (Keay et al, 2001a) (Table 14-2). It was found in bladder urine but not in renal pelvic urine of IC patients, indicating production by the bladder urothelial cells (Keay et al, 1999). Subsequent studies indicated that APF is associated with decreased production of heparin-binding epidermal growth factor-like growth factor (HB-EGF) (Keay et al, 2000, 2003). APF activity was related to increased production of epidermal growth factor (EGF), insulin-like growth factor-1, and insulin-like growth factor binding protein-3 by the bladder cells from IC patients but not by the cells from healthy bladders. Studies of IC patients and asymptomatic controls showed urine levels of APF, HB-EGF, and EGF to reliably separate IC from controls (Erickson et al, 2002; Keay et al, 2001b).

TABLE 14-2 Prevalence of Urine Antiproliferative Factor Activity in Interstitial Cystitis Patients and Control Groups

GROUPS	NO. OF PATIENTS POSITIVE/TOTAL	PERCENT POSITIVE
PATIENTS		
Interstitial cystitis	206/219	94
CONTROLS		
Asymptomatic	10/113	9
Overactive bladder	2/32	6
Bacterial cystitis	7/58	12
Microscopic hematuria	2/19	11
Stress incontinence	1/10	10
Neurogenic bladder	0/11	0
Benign prostatic hypertrophy	1/14	7
Nonbacterial prostatitis	1/16	6
Vulvovaginitis	0/12	0
Miscellaneous	1/16	6

From Keay SK, Zhang CO, Shoenfelt J, et al. Sensitivity and specificity of antiproliferative factor, heparin-binding epidermal growth factor-like growth factor, and epidermal growth factor as urine markers for interstitial cystitis. *Urology* 2001;57:9.

APF levels in the urine were found to discriminate between men with IC versus those with CPPS or nonbacterial prostatitis (Keay et al, 2004a). APF activity dropped significantly in IC patients within 2 hours after hydrodistention (Chai et al, 2000b) and after 5 days of sacral neuromodulation (Chai et al, 2000a). Cell culture studies showed that APF actually caused a decrease in HB-EGF and an increase in EGF, mirroring the differences in urine levels of these growth factors between IC patients and controls and suggesting that APF is the primary abnormality (Keay et al, 2003a).

Whereas APF may prove to be a useful marker for BPS/IC, it may also unlock the cause of the syndrome. It has been hypothesized by Keay and colleagues that BPS/IC may result from an inhibition of bladder epithelial cell proliferation caused by APF, which is mediated by its regulation of growth factor production from bladder cells (Keay et al, 2003b). Conceivably, any of a variety of injuries to the bladder (infection, trauma, and overdistention) in a susceptible individual may result in BPS/IC if APF is present and suppresses production of HB-EGF (Keay and Warren, 1998). Theoretically, if production of APF could be “turned off” by genetic techniques or its effects were nullified by an APF antagonist (Keay et al, 2011) or exogenous HB-EGF, the clinical syndrome might be prevented (Yang et al, 2012a). HB-EGF functionally antagonizes APF activity via a mitogen-activated protein kinase pathway activation (Kim et al, 2009a).

APF has been purified (Fig. 14-8) and proved to be a frizzled 8 protein that belongs to a newly discovered family of proteins that seem to be important in the development of nerve tissues, skin, and the lining of organs (Keay et al, 2004b). The frizzled family of receptors is critically involved in embryogenesis, and there is substantial evidence that members of this family also regulate tissue homeostasis in many different organs in the adult (Schulte and Bryja, 2007).

It appears that the cell cycle regulatory protein p53 is an important mediator of APF-induced effects on bladder epithelial cells (Kim et al, 2007). APF treatment suppresses cell proliferation by cell cycle arrest of human bladder urothelial cells. Evidence shows that p53 levels increase significantly after APF stimulation; p53 down-regulation enhances the suppressive effect of APF on cell growth; and overexpression of p53 induces cell cycle arrest in the absence of APF. APF upregulates cellular p53 levels via functional attenuation of the USP2a-MDM2 pathway, resulting in p53 accumulation and growth arrest (Kim et al, 2012). It is possible that targeting of p53 could be a means of abrogating the pathologic effects of urinary APF and lead to new options for clinical therapy.

Studies are ongoing to confirm the research by Keay and colleagues and expand on its significance in diagnosis and development of a rational treatment approach (Rashid et al, 2004). The development of animal models with specific signaling abnormalities found in BPS/IC epithelial, endothelial, smooth muscle, neuronal, or immune cells to determine whether these animals develop a disease similar to the human disorder would be an extremely useful and potentially very productive pathway to learning more about potential therapeutic pathways (Keay, 2008).

KEY POINTS: ANTIPROLIFERATIVE FACTOR

- The frizzled 8 protein termed *antiproliferative factor* (APF) has been proposed as a marker to identify patients with BPS/IC.
- It is secreted by bladder epithelial cells of BPS patients and inhibits bladder epithelial cell proliferation through mediation of growth factor production. Thus, it could be a proximal cause of the syndrome in many patients.

Neurobiology

Nonadrenergic noncholinergic mechanisms play significant roles in mediating direct functional effects as well as indirect effects by affecting inflammation (Vesela et al, 2012).

Figure 14-8. Composition and structure of antiproliferative factor (APF). (From Keay SK, Szekely Z, Conrads TP, et al. An antiproliferative factor from interstitial cystitis patients is a frizzled 8 protein-related sialoglycopeptide. *Proc Natl Acad Sci U S A* 2004;101:11803–8.)

Neuropeptides present in primary afferents and the dorsal horn of the spinal cord have an important role in the mediation of nociceptive input under normal conditions. Under pathologic conditions, such as during chronic inflammation or after peripheral nerve injury, the production of peptides and peptide receptors is dramatically altered, leading to a number of functional consequences (Wiesenfeld-Hallin and Xu, 2001). Inflammatory painful stimuli, especially if repeated, can chronically alter innervation, central pain-processing mechanisms, and tissue responses (Steers et al, 1997). It has been known for some time that the sensory nervous system can generate some of the manifestations of inflammation (Foreman, 1987; Dimitriadou et al, 1991, 1992). Activation of capsaicin-sensitive afferent neurons locally and centrally may be involved in stress-related pathologic changes in the rat bladder (Ercan et al, 2001). Activation of sensory nerves, specifically pain fibers, is known to trigger neurogenic inflammation through release of neuropeptides such as substance P, neurokinin A, and calcitonin gene-related protein, and subsequent increase in vascular permeability, with leukocyte adhesion and tissue edema. The neuropeptide mediators have been shown to also cause degranulation of mast cells with release of additional potent mediators of inflammation and to lead to injury and increased permeability of epithelial surfaces (Elbadawi and Light, 1996). An increase in nerve fibers within the suburothelium and detrusor muscle in ulcerative IC has been noted (Lundeberg et al, 1993). A correlation was found between the number of nerve fibers and numbers of mast cells as well as between the number of nerve fibers and the amount of histamine. Consolidating the leaky urothelium theory and mast cell activation, neurogenic inflammation is an attractive proposal for the cause and can readily accommodate infectious, immunologic, and autoimmunologic mechanisms as factors (Elbadawi and Light, 1996).

Harrison proposed that small-diameter sensory nerves in the bladder wall may have a role in the transmission of the sensation of pain and in the triggering of inflammatory reactions rather than forming the afferent limb of the micturition reflex (Harrison et al, 1990). Abelli demonstrated in the rat urethra that mechanical irritation alone can cause neuropeptide release from peripheral capsaicin-sensitive primary afferent neurons, resulting in neurogenic inflammation (Abelli et al, 1991). Extracellular ATP can act through the purinergic receptor subtype P2X₃ to transmit a pain signal to the central nervous system. These subunits expressed by

cultured IC bladder urothelial cells are upregulated during in vitro stretch and may phenotypically mimic sensory neurons (Sun and Chai, 2004). Purinergic receptor antagonists that are orally bioavailable may provide an avenue for a potential therapeutic strategy (Burnstock, 2012).

Several pieces of additional information support a theory of neurogenic inflammation. Levels of nerve growth factor are elevated in bladder biopsy specimens from IC patients (Lowe et al, 1997), providing another potential therapeutic target (Ochodnick et al, 2011). Studies in rats using pseudorabies virus clearly show that bladder inflammation can be induced from a somatic structure through a neural mechanism and that central nervous system dysfunction can bring about a peripheral inflammation (Doggweiler et al, 1998). Pelvic nerve stimulation in the rat increases urothelial permeability, which is antagonized by capsaicin, indicating both an efferent effect of afferent nerves and afferent mediated neuroepithelial interaction (Lavelle et al, 1999). Ca²⁺/calmodulin-dependent protein kinase II has been implicated in the neurogenic cystitis pelvic pain induced in a mouse model with pseudorabies virus infection (Yang et al, 2012b).

Numerous studies indicate increased sympathetic activity in IC. Hohenfellner suggested that IC is associated with increased sympathetic outflow into the bladder and altered metabolism of vasoactive intestinal polypeptide and NPY (Hohenfellner et al, 1992). NPY inhibits bladder afferents and therefore may be involved in autonomic disturbances affecting the bladder. Elevation of urinary catecholamines in IC patients and plasma catecholamines in cats with FIC has been observed (Stein et al, 1999; Buffington and Pacak, 2001), as has an increased density and number of nerve fibers immunoreactive for tyrosine hydroxylase in IC patients (Peeker et al, 2000a). Whether these changes reflect a cause of IC or are merely the result of long-standing intense pain and a severely pathological voiding pattern is unknown.

Galloway proposed that the changes in IC may be explained by an increase in sympathetic discharge, analogous to that seen in reflex sympathetic dystrophy (RSD) of limbs (Galloway et al, 1991). The pathology in RSD is the development of abnormal synaptic activity between sensory afferent and sympathetic efferent neurons. Nerve cells in the spinal cord become hypersensitive to sensory input, and this sustains abnormal sympathetic outflow and corresponding vasomotor dysregulation. The excess sympathetic outflow leads to constriction of blood vessels and tissue ischemia,

setting up further sensory changes and perpetuating the cycle. In RSD, there is usually a trigger event leading to these changes. With the acute phase of RSD, regional signs of inflammation are evident in the affected extremity. One school of thought believes an inflammatory response to an injury initiates RSD. Increased capillary permeability is a direct result (Goris and Jan, 1998). Perhaps a urinary infection could trigger such a pathologic cycle in some IC patients?

Herbst produced bladder lesions in a dog resembling the ulceration of IC by ligating the blood vessels to the posterior bladder wall and infecting the area with *Streptococcus viridans* (Herbst et al, 1937). Studies using laser Doppler flowmetry have shown that when the bladder is distended under anesthesia, blood flow increases in control patients to a statistically significant degree as compared with IC patients (Irwin and Galloway, 1993; Pontari et al, 1999). Another study has purported to show that topical heparin therapy can normalize urothelial permeability and vesical blood flow in IC (Hohlbrugger et al, 1998). Decreased microvascular density has been described in the suburothelium but not in the deeper mucosa in bladder biopsy specimens from women with IC (Rosamilia et al, 1999a). Hyperbaric oxygen has been suggested to have a limited effectiveness for the treatment of BPS/IC (van Ophoven et al, 2004b, 2006; Tanaka et al, 2007; Loran et al, 2011; Tanaka et al, 2011; Gallego-Vilar et al, 2013) as well as radiation-induced cystitis (Weiss and Neville, 1989). The mechanism of action has been postulated to be related to the overexpression of hypoxia-inducible factor-1 and VEGF in BPS/IC bladders (Lee and Lee, 2011).

If lumbar sympathetic blocks can decrease the pain of IC, a role of the sympathetic nervous system in IC pathogenesis is a reasonable supposition (Irwin et al, 1993; Doi et al, 2001). Buffington has demonstrated an increase in sympathetic activity in cats with FIC (Buffington and Pacak, 2001; Buffington et al, 2002). Similar findings have been reported in a small study of IC patients (Dimitrakov et al, 2001), and sympathetic activity may be an underlying common denominator in many disorders associated with PBS/IC (Buffington, 2004).

Nevertheless, no studies performed to date indicate that any case of IC is related to the syndrome of RSD (chronic regional pain syndrome) (Ratliff et al, 1994). No single test can be used to exclude sympathetically maintained pain, and there are no clear symptoms that predict sympathetically mediated pain (Baron, 2000). In the animal model, bladder ischemia is associated with DO or impaired detrusor contraction, not sensory urgency (Azadzi et al, 1999). Patients with RSD who have voiding symptoms rarely have a picture that would be confused with IC (Chancellor et al, 1996).

Before leaving the neurogenic causative theory, it is important to note that the nervous system itself almost surely contributes to the chronic nature of this pain syndrome, regardless of initiating cause (Vrinten et al, 2001). Repetitious stimulation of a peripheral nerve at sufficient intensity to activate C fibers results in a progressive buildup of the magnitude of the electrical response recorded in the second-order dorsal horn neurons. This "windup" phenomenon is central to the concept of chronic pain. Biochemically it is dependent on activation of *N*-methyl-D-aspartate (NMDA) receptors in the spinal cord (Bennett, 1999). With persistent NMDA receptor activation, spinal cord cells undergo trophic changes, and the pain resulting from subsequent stimulation becomes exaggerated and prolonged. This "pain memory" in the spinal cord may be what causes IC patients to become refractory to different therapies (Brookoff and Sant, 1997). NMDA-receptor-driven formation of new connections in the spinal cord may account for the expansion of the pain field.

Upregulation of the CNS and augmented sensory processing have been referred to as non-nociceptive pain (NNP) (Bennett, 1999). The four characteristic features of NNP would seem to apply very well to the clinical syndrome of IC (Box 14-4). Chronic neuropathic pain may continue after the resolution of tissue damage and persist on the basis of a maladaptive mechanism (Urban et al, 2002).

BOX 14-4 Non-Nociceptive Pain: Characteristic Clinical Features

1. The description of the pain seems inappropriate in comparison with the degree of tissue pathology, or no tissue pathology may be discernible.
2. Noxious stimuli result in a pain experience that is greater and more unpleasant than would normally be expected (hyperalgesia).
3. Normally non-noxious stimuli may result in pain (allodynia).
4. The extent of the pain boundary is greater than would be expected on the basis of the site of the original tissue pathology.

From Bennett RM. Emerging concepts in the neurobiology of chronic pain: evidence of abnormal sensory processing in fibromyalgia. *Mayo Clin Proc* 1999;74:385–98.

Burnstock's observation that ATP has a role in mechanosensory transduction by the epithelial lining of hollow viscus organs such as bladder (Burnstock, 1999) has been followed up by Sun and colleagues. Stretched epithelial cells lining hollow organs release ATP, which acts on purinergic nociceptive receptors on subepithelial sensory nerve terminals. ATP was significantly elevated in the urine of PBS/IC patients, and the stretch-activated release of ATP was augmented in IC urothelium (Sun et al, 2001).

Neurogenic inflammation may be the cause of some cases of BPS or may be the result of other initiating causative events. It is not incompatible with the central role of the mast cell, or with the leaky epithelium theory. It conceivably could result in the appearance of autoimmune phenomena or result from an episode of infection. The central nervous system may also be implicated in dysregulation of the pelvic floor resulting in chronic pelvic pain and contributing to IC (Zermann et al, 1999), and perhaps in the rare cases of IC that chronologically seem to relate to trauma or pelvic surgery (Zermann et al, 1998). It is an etiologic theory that provides fertile ground for new treatment possibilities.

KEY POINTS: NEUROGENIC INFLAMMATION

- Numerous studies indicate increased sympathetic activity in BPS/IC. Activation of sensory pain fibers is known to trigger neurogenic inflammation through release of neuropeptides such as substance P, neurokinin A, and calcitonin gene-related protein.
- Neurogenic inflammation may be the cause of some cases of BPS/IC. Chronic neuropathic pain may continue after the resolution of tissue damage and persist on the basis of a maladaptive mechanism.

Pelvic Organ Cross-Sensitization

Clinical observations of viscerovisceral referred pain in patients with gastrointestinal and genitourinary disorders suggest an overlap of neurohumoral mechanisms underlying both bowel and urinary bladder dysfunctions. Close proximity of visceral organs within the abdominal cavity complicates identification of the exact source of chronic pelvic pain, where it originates, and how it relocates with time. Cross-sensitization among pelvic structures may contribute to chronic pelvic pain of unknown cause and involves convergent neural pathways of noxious stimulus transmission from two or more organs. **Inflammation, nerve injury, ischemia, peripheral hyperalgesia, metabolic disorders, and other pathologic conditions can dramatically alter the function of directly affected**

pelvic structures as well as organs located next to a damaged domain (Malykhina, 2007). It has been demonstrated in a rat model that acute colitis can sensitize lumbosacral spinal neurons receiving input from the urinary bladder (Qin et al, 2008). Acute colitis and acute cystitis in the rat model can each cross-sensitize the bladder and colon, respectively (Pezzone et al, 2005).

It is thought that chronic widespread pain in chronic fatigue syndrome and fibromyalgia (disorders associated with BPS/IC in many patients) can be a consequence of central sensitization. Central sensitization is an increased central neuronal responsiveness and causes hyperalgesia, allodynia, and referred pain and hyperalgesia across multiple spinal segments, leading to chronic widespread pain. Triggers include windup or temporal summation, dysregulated descending inhibitory pathways, and upregulated facilitatory modulation. Windup or temporal summation is the result of repetitive noxious stimuli, leading to an increase in electrical discharges in the dorsal horn. Inhibitory modulation can be impaired by abnormalities in the central nervous system, and the facilitatory pain pathways can be stimulated by certain behavioral and cognitive factors (Meeus and Nijs, 2007).

It is possible that a combination of central sensitization and pelvic cross-talk may account for the association of BPS/IC with bowel symptoms in some patients, and the use of dietary alterations for managing the severity of BPS symptoms. Relatively minor gut stimuli that otherwise cause no symptoms could exacerbate established, bladder-driven pelvic pain, because even slight increases of inputs from a second site such as the gut might lead to a sum of inputs that is considerably elevated above a threshold necessary to induce pain (Rudick et al, 2007; Klumpp and Rudick, 2008). Central pain amplification might also account for the increased startle responses described in female BPS/IC patients in the context of a threat of abdominal pain (Twiss et al, 2009).

KEY POINTS: SENSITIZATION OF NEURAL PATHWAYS

- Cross-sensitization among pelvic structures may contribute to CPPS.
- Neural pathways from two or more organs, one or both of which are carrying noxious stimuli transmissions, may converge. Theoretically, this could lead to alteration of the function of not only the directly affected pelvic structures, but organs located nearby as well.

Nitric Oxide Metabolism

Regulation of urinary NOS activity has been proposed to be of importance for immunologic responses in BPS. The oral administration of L-arginine, the substrate for nitric oxide production (Moncada and Higgs, 1993), has been shown to increase nitric oxide-related enzymes and metabolites in the urine of patients with BPS (Smith et al, 1996). It has been reported that differences in nitric oxide evaporation between ulcerative and nonulcerative BPS allows for subtyping of cases meeting the NIDDK criteria. This could potentially replace cystoscopy as a tool for identifying ulcerative BPS/IC (Logadottir et al, 2004). Increased levels of endogenously formed nitric oxide correspond to increased iNOS in mRNA expression and protein levels in BPS patients. iNOS has been found to be localized to the urothelium and has also been found in macrophages in the bladder mucosa. Whether high levels of endogenously formed nitric oxide are a part of the pathogenesis in BPS/IC and whether it has a protective or damaging role remains to be elucidated (Koskela et al, 2008).

Urine Abnormalities

In general, current theories of pathogenesis involve access of a component of urine to the interstices of the bladder wall, resulting in an inflammatory response induced by toxic, allergic, or

immunologic means. The substance in the urine may be a naturally occurring one—a substance that acts as an initiator only in particularly susceptible individuals—or may act like a true toxin, gaining access to the urine by a variety of mechanisms or metabolic pathways (Wein and Broderick, 1994). Clemmensen noted that 8 of 11 IC patients had positive skin reactions to patch tests with their own urine (Clemmensen et al, 1988). Immediate reactions were not observed, and the histology suggested a toxic rather than an allergic reaction. Lynes was unable to find a urinary myotropic substance unique to IC patients (Lynes et al, 1990b). The San Diego group found IC urine to result in higher cell death of cultured transitional cells than normal urine, suggesting a toxic compound in the urine of some IC patients (Parsons and Stein, 1990). They identified heat-labile, cationic components of low molecular weight that bind to heparin and that, when separated from the bulk of urinary wastes, are cytotoxic to urothelial cells as well as underlying smooth muscle cells (Parsons et al, 2000). They reported a 12% increase in 72-kDa stress protein in cells treated with urine from IC patients compared with controls (Ito et al, 1998).

Others have not been able to demonstrate in vitro cytotoxicity (Beier-Holgersen et al, 1994) or immunohistochemical changes in the nociceptive centers in the spinal cord or bladder wall when IC urine was compared with control urine (Baykara et al, 2003). Efforts to induce an IC-like picture in the rabbit bladder from exposure to urine of IC patients have failed to demonstrate conclusive changes (Perzin et al, 1991; Ruggieri et al, 1993; Kohn et al, 1998). Increased levels of soluble mediators associated with activation of sensory neurons and/or mast cells have been found in the urine of both IC and bladder cancer patients (Okragly et al, 1999).

Circumstantial evidence for the toxicity of IC urine is suggested by the failure of substitution cystoplasty and continent diversions in some of these patients because of the development of pain or contraction of the bowel segment over time (Nielsen et al, 1990; Baskin and Tanagho, 1992; Trinka et al, 1993; Lotenfoe et al, 1995), and by the histologic findings similar to IC found to occur in bowel used to augment the small-capacity IC bladder (McGuire et al, 1973; Singh and Thomas, 1996). Intestinal mucosa in contact with urine undergoes progressive changes for as long as 3 years after surgery, and the significance of the histologic IC-like changes has been questioned (MacDermott et al, 1990; Davidsson et al, 1996).

Role of Genetics in Bladder Pain Syndrome

Warren and colleagues (2001b) reported findings from a small cohort of twins in which a greater concordance of BPS was demonstrated among monozygotic than among dizygotic twins. This finding suggested that there could be a genetic susceptibility to BPS. A later study by the same research group (Warren et al, 2004) suggested that adult female first-degree relatives of patients with BPS may have a prevalence of IC 17 times that found in the general population. This, coupled with the previously reported twin data, suggests but does not prove that a genetic component adds to the susceptibility to BPS. Looking at an identical twin model with 246 twin sisters, Tunitsky and colleagues found that 9% were identified as having a moderate or high risk of BPS, with 5 twin sets in which both twins met the criteria. They concluded that BPS symptom scores within twin pairs were moderately correlated, implying some genetic component (Tunitsky et al, 2012).

A Swedish study that included more than 25,000 twins born from 1959 to 1985 compared monozygotic and dizygotic twins with symptoms of BPS. Overall BPS prevalence was 1.1% of men and 2.4% of women. In women, genetic factors contributed less than one third of the total variation in susceptibility to BPS. Lower male prevalence prevented determinations of genetic contribution. The authors concluded that the influence of environmental factors in the development of BPS in women is substantial, whereas genetic influences are of only modest importance (Altman et al, 2011).

The report by Weissman and colleagues (2004) of the increased frequency of BPS in patients and their first-degree relatives with panic disorder and other seemingly disparate disorders has suggested that there is a familial syndrome consisting of BPS and other

disorders of possible autonomic or neuromuscular dysfunction. A more recent case-control study by the same group (Talati et al, 2008) suggested that this syndrome might include other anxiety disorders as well, and that families with and without this collection of symptoms were genetically distinguishable on chromosome 13.

Gene expression profiles in cultured IC cells have been investigated and compared with controls (Erickson et al, 2008a). Few differences were appreciated, indicating that rather than being genetically based, the abnormal urothelium in BPS/IC may be caused by post-translational changes and/or to the bladder environment. It has been suggested that epigenetic reprogramming mechanisms in the bladder may provide an explanation for uroepithelial, mast cell, and nerve cell abnormalities in BPS/IC, as well as propagation of this altered state in the absence of the signal that may have triggered it (Elgavish, 2009). Viewing medically unexplained symptoms from the perspective of underlying developmental influences involving epigenetic modulation of gene expression that affect function of a variety of organs based on familial predispositions rather than from the traditional viewpoint of isolated organ-originating diseases may open up new areas of investigation for this class of “functional” disorders (Buffington, 2009).

Other Potential Causes

Various other etiologic theories have been proposed (Ratliff et al, 1994), but none has received much scientific support. Voiding almost hourly, always having to be aware of how far the nearest restroom facilities are, and suffering constant pain would be expected to lead to psychological stress. However, could there be individual differences in the propensity to develop BPS/IC that result from a dysregulation of anxiety and mood (Nesse, 1999; Bodden-Heidrich, 2004)? Childhood sexual trauma has been implicated as a causative factor for the disease (Mayson and Teichman, 2009; Tietjen et al, 2010; Nickel et al, 2011). **There are no data currently to suggest that stress itself initiates the chronic syndrome of BPS/IC, although it certainly can increase symptom severity (Lutgendorf et al, 2000).** Cats restricted to indoor living are five times more likely to have urinary problems than cats allowed outdoors (Buffington et al, 2002). Female patients with BPS/IC have been shown to have increased heart rate at baseline and throughout a laboratory mental stress challenge, but did not demonstrate greater autonomic reactivity to stress (Lutgendorf et al, 2004). Until stress can be shown to produce BPS/IC de novo in humans, it is just as reasonable to speculate that the stress is a result of the syndrome as a primary cause of it.

Speculation that abnormality in or obstruction of lymphatics or vascular structures is causative has never been borne out. The fact that some of these patients have had hysterectomy probably relates more to the attempt of the physician to treat chronic pelvic pain than to postsurgical change as a cause of the IC syndrome (Chung, 2004).

The knowledge that there is at least a 5:1 female-to-male preponderance immediately makes the role of the hormonal milieu potentially important (Bjorling and Wang, 2001). Paradoxically, it is known that estrogens can control hematuria in hemorrhagic cystitis, perhaps by decreasing the fragility of the mucosal microvasculature of the bladder (Liu et al, 1990). Estradiol augments whereas the estrogen receptor blocker tamoxifen inhibits mast cell secretion (Vliagoftis et al, 1992). Bladder mast cells express high-affinity estrogen receptors, and there is a higher number of such cells present in patients with IC compared with controls. Although this may help explain why IC is so common in women, the hormonal role can only account for the propensity of IC to occur in females, not the ultimate cause.

Pelvic floor dysfunction has been associated with BPS/IC for many years (Schmidt and Vapnek, 1991), and trials suggest that treatment of the pelvic floor can be effective in ameliorating symptoms (Lilius et al, 1973; Doggweiler-Wiygul et al, 2001; Holzberg et al, 2001; Weiss, 2001; Doggweiler-Wiygul et al, 2002; Oyama et al, 2004; FitzGerald et al, 2012). Speculation that abnormalities of the pelvic floor muscular function may contribute to the cause of some cases of CPPS in men is well accepted (Segura et al, 1979; Schmidt and Vapnek, 1991; Zermann et al, 1999), and a similar case might be made for patients with BPS/IC, though scientific support for a direct causative relationship is lacking.

One can understand the complexity of BPS/IC by looking at the myriad theories of etiology and the associated disorders that have been described. Complex functional disorders with patterns of comorbidity, in which there is overlap of what had once been regarded as independent syndromes, appear to fall outside the biomedical framework. It has been said that they “fully escape the profession’s divided and divisive grip. By their mere existence, they challenge the medical community’s view of the body, their understanding of what it is to be human and question whether present approaches to obtaining knowledge are adequate for helping people who suffer” (Kirkengen and Ulvestad, 2007).

KEY POINT: ETIOLOGY

- Both stress and pelvic floor dysfunction can contribute to BPS symptom severity and may be targets for treatment. Whether they can be contributing initiators of the syndrome complex is unclear at this time. The 5:1 female preponderance suggests hormonal involvement in the cause, but if recent data suggest that male prevalence is close to female prevalence, this conventional wisdom will need revision (Suskind et al, 2013a).

patients and reported a linear relationship between the mean bladder capacity under anesthesia and severity of glomerulations (Hanus et al, 2001). They did not find a correlation between severity of symptoms and histopathologic changes observed with light or electron microscopy.

Rosamilia reviewed the pathology literature pertaining to BPS and presented her own data (Rosamilia et al, 2003; Hanno et al, 2005a). She compared forceps biopsy specimens from 35 control and 34 BPS/IC patients, 6 with bladder capacities less than 400 mL under anesthesia. Epithelial denudation, submucosal edema, congestion and ectasia, and inflammatory infiltrate were increased in the BPS group. Submucosal hemorrhage did not differentiate the groups, but denuded epithelium was unique to the BPS group and more common in those with severe disease. The most remarkable finding in her study was that histologic parameters were normal and indistinguishable from control subjects in 55% of BPS subjects. Method of biopsy can be important in interpreting findings, because transurethral resection biopsy specimens tend to show mucosal ruptures, submucosal hemorrhage, and mild inflammation (Johansson and Fall, 1990), whereas histology is normal approximately half the time with cold-cup forceps biopsy specimens (Mattila, 1982; Lynes et al, 1990a; Rosamilia et al, 2003).

Histopathology plays a supportive diagnostic role at best (Johansson et al, 1997). Major reconstructive procedures appear to have better outcomes in patients with pathology consistent with Hunner lesions (Rössberger et al, 2007). Inflammatory features can be seen in 24% to 76% of patients without a visible Hunner lesion (Erickson et al, 2008b). Although studies have suggested that a severely abnormal pathology may be associated with poor prognosis (McDougald and Landon, 2003; Nordling et al, 2004), this is not necessarily the case (MacDermott et al, 1991a). At this point in time, excluding other diseases that are pathologically identifiable is the primary clinical use of bladder biopsy in this group of patients.

KEY POINTS: PATHOLOGY

- The role of histopathology is primarily to exclude other possible diagnoses that might be responsible for the symptoms.
- There is no histology pathognomonic of BPS, and one cannot make the diagnosis on pathology alone in the absence of the cardinal symptoms.
- Completely normal-appearing bladder biopsy specimens in symptomatic patients are not uncommon.

DIAGNOSIS

BPS/IC can be considered a functional pain disorder (Mayer and Bushnell, 2009) and one of the chronic visceral pain syndromes affecting the urogenital and rectal area, many of which are well described but poorly understood (Wessellmann et al, 1997; Wessellmann, 2001). These include vulvodynia, orchalgia, penile pain, perineal pain, and rectal pain. In men, many of the entities have now been included in the rubric of CPPS and can be difficult to distinguish from BPS/IC (Hakenberg and Wirth, 2002; Forrest and Schmidt, 2004). The diagnosis of BPS/IC is by its very nature based on the definition. In the past this was, by default, the symptom criteria enumerated by the NIDDK (Hanno et al, 1999a, 1999b) (see Box 14-2). It has now morphed largely into a diagnosis of chronic pain, pressure, or discomfort associated with the bladder, usually accompanied by urinary frequency in the absence of any identifiable cause (Hanno et al, 2005a, 2005b). Diagnostic approaches vary widely, and general agreement on a diagnostic algorithm remains a future goal (Chai, 2002; Nordling, 2004; Nordling et al, 2004). The disorder can be very difficult to diagnose until symptoms become well established, unless one has a high level of suspicion (Porru et al, 2004). Frequency and pelvic pain of long duration perceived to be related to the bladder unrelated

to other known causes establishes a working diagnosis. It is often difficult for patients to distinguish between sensations of pain, pressure, discomfort, and urgency. Ask a patient why he or she voids hourly, and the patient usually will state that it is because of discomfort rather than convenience. Heavy reliance on other aspects of the NIDDK research criteria will result in underdiagnosing more than half of patients (Hanno et al, 1999b). IC symptom scales (O'Leary et al, 1997; Goin et al, 1998; Moldwin and Kushner, 2004), such as the AUA symptom score for BPH, are designed to evaluate the severity of symptomatology and monitor disease progression or regression with or without treatment. They have not been validated as diagnostic criteria.

One must rule out infection and less common conditions including but not limited to carcinoma (Utz and Zincke, 1974; Tissot et al, 2004), eosinophilic cystitis (Hellstrom et al, 1979; Sidh et al, 1980; Littleton et al, 1982; Aubert et al, 1983; Abramov et al, 2004), malakoplakia, schistosomiasis, scleroderma (Batra and Hanno, 1997), and detrusor endometriosis (Sircus et al, 1988; Price et al, 1996). In men under the age of 50, video-urodynamics are useful to rule out voiding dysfunction resulting from vesical neck obstruction, "pseudo" dyssynergia, or impaired contractility (Kaplan et al, 1996). Musculoskeletal dysfunction may also play a role in causation or increasing symptom severity and should be looked for in the diagnostic phase of evaluation (Prendergast and Weiss, 2003). Reports of successful treatment of IC symptoms by laparoscopic adhesiolysis (Chen et al, 1997) or urethral diverticulum excision (Daneshgari et al, 1999) give credence to the fact that IC is a diagnosis of exclusion. Many drugs including cyclophosphamide, aspirin, nonsteroidal anti-inflammatory agents, and allopurinol have caused a nonbacterial cystitis that resolves with drug withdrawal (Bramble and Morley, 1997; Gheyi et al, 1999).

Ketamine hydrochloride, commonly used as an anesthetic agent, is an NMDA receptor antagonist. It has a rapid onset and short duration of action and produces a cataleptic-like state wherein the patient is dissociated from the surrounding environment by direct action on the cortex and limbic system. In some parts of the world such as Taiwan, it is an increasingly popular choice among young drug users, especially within dance club venues. It can cause dysuria, lower urinary tract symptoms, pelvic pain, and impaired bladder functional capacity. At endoscopy, ulceration with severe diffuse bladder hemorrhage and low capacity has been described (Chen et al, 2011; Middela and Pearce, 2011). Decreased E-cadherin and increased apoptosis are more severe in ketamine cystitis than BPS (Lee et al, 2013). Treatment is cessation of abuse of the drug.

Tarlov cysts are present in 4.6% of the population. When present at lumbosacral levels, symptoms may include perineal pressure and pain and voiding hallmarks of BPS. Successful treatment with epidural steroids has been reported (Freidenstein et al, 2012).

Various gynecologic problems can mimic the pain of IC (Kohli et al, 1997). The pelvic congestion syndrome, a condition of the reproductive years and equally prevalent among parous and nulliparous women, manifests with shifting location of pain, deep dyspareunia and postcoital pain, and exacerbation of pain after prolonged standing (Stones, 2003). Similar symptoms can be seen in BPS/IC. Other gynecologic disorders can include pelvic tumors, vaginal atrophy, vulvodynia, vestibulitis, pelvic relaxation, pelvic adhesive disease, levator ani myalgia, and undiagnosed chronic pelvic pain (Myers and Aguilar, 2002). Pelvic surgery is more common in women with a diagnosis of BPS/IC than in a control population (Ingber et al, 2008). In Ingber's series, the diagnosis of BPS/IC occurred 1 to 5 years after hysterectomy in most patients, suggesting that pelvic surgery may be performed for pain related to undiagnosed BPS.

Endometriosis can be a cause of pelvic pain (Evans et al, 2007), an idea largely based on findings of two randomized, placebo controlled studies of laser laparoscopy (Sutton et al, 1995, 1997; Abbott et al, 2004). Nevertheless, it is disconcerting that any claim linking endometriosis with pain fails to account for the common experience that identical lesions can be found in symptomatic and asymptomatic women (Vercellini, 1997). From 2% to 43% of

asymptomatic women are found to have endometriosis (Moen and Stokstad, 2002). Furthermore, there does not appear to be any risk for patients with asymptomatic mild endometriosis to develop symptoms even after more than 10 years (Moen and Stokstad, 2002). Although 70% to 90% of women with chronic pelvic pain have endometriosis, this does not definitively establish causation (Gambone et al, 2002). For these reasons, laparoscopy, which is not considered essential before initiation of hormonal treatment of endometriosis (Ling, 1999; Howard, 2003b), should not be considered a part of any routine evaluation of BPS/IC unless an experienced practitioner believes it is likely to benefit the patient.

A presumptive diagnosis can be made merely by ruling out known causes of frequency, pain, and urgency in a patient with compatible chronic symptoms (Box 14-5). This holds true for adolescents as well as adults (Yoost et al, 2012). Often this will involve a complete history, physical examination, appropriate cultures, and local cystoscopy. A finding of tenderness on examination

of the anterior vaginal wall with an empty bladder at the initial examination can lead one to suspect BPS (Paulson and Paulson, 2011). In the absence of microhematuria the value of cytology is questionable (Duldulao et al, 1997), but it is something we still consider important, especially if bladder carcinoma in situ is a serious possibility, as in patients older than 40 and those with a smoking history. The report of a large series of BPS/IC patients indicating that 1% actually had transitional cell carcinoma and that four of the six cancer patients did not have microhematuria provides evidence for the justification of local cystoscopic examination (Tissot et al, 2004).

It must be recognized that one may sacrifice a certain level of confidence in the diagnosis without the supporting evidence that can be furnished by additional studies. In a long-term illness such as BPS/IC, many patients and physicians ultimately want to base a diagnosis and treatment plan on the most complete data set possible (Rovner and Wein, 1999). A more thorough evaluation would also include a urodynamic evaluation and cystoscopy under anesthesia with hydrodistention of the bladder (Hanno et al, 1990; Hanno, 1994b). Bladder biopsy is indicated only if necessary to rule out other disorders that might be suggested by the cystoscopic appearance. Cystoscopy under anesthesia with bladder distention has been important in the identification of a Hunner lesion. Experimental data suggest that measurement of increased nitric oxide levels in the bladder can also accurately identify those with ulcerative disease (Logadottir et al, 2004). In general, the diagnosis is subject to more rigorous testing in Europe (Fall et al, 2008) than in North America, where symptoms in the absence of other obvious causes seems to be the gold standard (Nordling, 2004; Nordling et al, 2004; Hanno et al, 2005a). Japanese guidelines are listed in Box 14-6.

Although sensations reported during cystometric bladder filling are subjective, they have a normal pattern and may be helpful in distinguishing bladder pathology (Wyndaele, 1998). Many dispute the need for urodynamic study (Cameron and Gajewski, 2009), but Siroky and Kim argue that not only can it help to assess

BOX 14-5 International Consultation on Incontinence 2009: Diagnosis of Bladder Pain Syndrome

HISTORY

General thorough medical history emphasizing the following:

1. Previous pelvic surgery
2. Previous urinary tract infection
3. Bladder history and urologic diseases
4. Location of pelvic pain and relationship to bladder filling and emptying
5. Characteristics, onset, correlation of pain with other events
6. Previous pelvic irradiation
7. Autoimmune diseases
8. Associated syndromes (irritable bowel, fibromyalgia, chronic fatigue)

PHYSICAL EXAMINATION

Physical examination emphasizing the following:

1. Standing: kyphosis, scars, hernia
2. Supine: abduction and adduction of hips, hyperesthetic areas
3. Females: vaginal examination with pain mapping of vulvar region, vaginal palpation for tenderness of the bladder, urethra, levator and adductor muscles of the pelvic floor
4. Males: digital rectal examination with pain mapping of the scrotal-anal region and palpation of tenderness of the bladder, prostate, levator and adductor muscles of the pelvic floor and scrotal contents

LABORATORY TESTING

1. Urinalysis
2. Urine culture
3. Urine cytology in risk groups

SYMPTOM EVALUATION

1. Voiding diary
2. O'Leary-Sant symptom and problem index
3. Visual analog scale for pain in the last 24 hours

OTHER EVALUATIONS

Urodynamics (optional)
Cystoscopy with or without hydrodistention under anesthesia (optional)
Bladder biopsy (optional)

BOX 14-6 Recommended Tests for Diagnosis of Interstitial Cystitis from the Japanese Urological Association

MANDATORY

Clinical history
Physical examination
Urinalysis

RECOMMENDED

Urine culture
Urine cytology
Symptom scores
Quality-of-life scores
Frequency-volume chart
Residual urine measurement
Prostate-specific antigen
Cystoscopy
Hydrodistention

OPTIONAL

Ultrasonography
Urodynamic study
X-ray examination
Potassium test
Biopsy

bladder compliance and sensation and reproduce the patient's symptoms during bladder filling, but it can help to rule out DO (Siroky, 1994; Kim et al, 2009b). Women with pain on filling can be indistinguishable from those with DO in their perception of bladder fullness (Creighton et al, 1991). One should be wary of diagnosing BPS/IC in patients with discrete, involuntary bladder contractions whose symptoms respond to antimuscarinic therapy. The two problems may coexist in 15% to 19% of patients (Gajewski et al, 1997; Kirkemo et al, 1997), but the pathophysiology is possibly very different. Patients who respond to anticholinergic medication tend not to respond to standard therapy for BPS (Perez-Marrero et al, 1987). If involuntary contractions are noted and the patient's symptoms of frequency and pain continue despite treatment for overactive bladder, one is on firmer ground in considering a diagnosis of BPS/IC. Complex cases may benefit from full video-urodynamic studies (Carlson et al, 2001).

Cystometry in conscious BPS patients typically demonstrates normal function, the exception being decreased bladder capacity and hypersensitivity. Pain on bladder filling that reproduces the patient's symptoms is very suggestive of the diagnosis. Volume at strong desire to void has been purported to be a predictor of treatment outcome (Kuo and Kuo, 2013). Bladder compliance in patients with BPS/IC is normal, as hypersensitivity would prevent the bladder from filling to the point of noncompliance (Siroky, 1994; Rovner and Wein, 1999). The possible addition of a second cystometrogram after instillation of intravesical lidocaine to help determine if pain is bladder related is a provocative issue worth further study (Teichman et al, 1997). It is not uncommon to find evidence of outlet obstruction in BPS/IC, presumably related to associated pelvic floor dysfunction (Cameron and Gajewski, 2009).

Long before it was considered a diagnostic tool, CHD was used as a therapeutic modality for BPS (Bumpus, 1930). CHD under anesthesia allows for sufficient distention of the bladder to afford visualization of either glomerulations (Fig. 14-9) or Hunner lesions (Fig. 14-10). After filling to 80 cm water pressure for 1 to 2 minutes, the bladder is drained and refilled. The terminal portion of the effluent is often blood tinged. Reinspection will reveal the pinpoint petechial hemorrhages that develop

Figure 14-10. Typical appearance of Hunner lesion in a patient with bladder pain syndrome before bladder distention.

throughout the bladder after distention and are not usually seen during examination without anesthesia (Nigro et al, 1997b).

Glomerulations are not specific for BPS/IC (Erickson, 1995; Waxman et al, 1998), and only when seen in conjunction with the clinical criteria of pain and frequency can the finding of glomerulations be viewed as potentially significant. Glomerulations can be seen after radiation therapy, in patients with carcinoma, after exposure to toxic chemicals or chemotherapeutic agents, and

often in patients on dialysis or after urinary diversion when the bladder has not filled for prolonged periods. They have been reported in the majority of men with prostate pain syndromes, begging the question as to whether CPPS in men is closely linked with IC (Berger et al, 1998). They are observed in up to 20% of men undergoing transurethral prostatectomy for lower urinary tract symptoms (Furuya et al, 2007). We have speculated that they may simply reflect the response of the bladder to distention after a prolonged period of chronic underfilling because of sensory urgency, rather than resulting from a primary pathologic process. Although the presence of a Hunner ulcer has been associated with pain and urinary urgency, neither the finding of bloody irrigating fluid nor of glomerulations is strongly associated with any particular symptom in patients in the ICDB (Messing et al, 1997).

Further confusion arises when the patient demonstrates the symptoms of IC but the cystoscopic findings under anesthesia are completely normal. This occurred in 8.7% of patients undergoing CHD entered into the IC database (Messing et al, 1997). Awad and colleagues recognized this entity soon after the NIDDK research criteria had been described. They reported on a series of patients in whom the symptomatology, urodynamic evaluation findings, histology, and response to therapy were identical to IC but in whom findings on CHD were normal. It was termed *idiopathic reduced bladder storage* (Awad et al, 1992). Clinical, urodynamic, and cystoscopic data strongly suggest that the presence of glomerulations is not selecting out a meaningful difference in patients with symptoms of BPS/IC (Al Hadihi et al, 2002). The presence of cystoscopic abnormalities such as glomerulations on cystoscopy under anesthesia meeting the NIDDK criteria may identify a group of patients with worse daytime frequency and nocturia, lower mean voiding volumes, and lower bladder capacity under anesthesia, but does not have any relationship to biopsy findings, bladder pain, or urgency (Erickson et al, 2005; Boudry et al, 2013).

The Search for a Marker

What is the value of a “diagnostic test” in what is essentially a clinical syndrome defined by a symptom complex? If a patient has chronic pain associated with the bladder usually accompanied by urinary frequency with no discernible cause, we diagnose BPS/IC. In essence, once we have ruled out well-characterized pathologic entities, the patient makes the diagnosis by relating symptoms, much as a patient with impotence makes that diagnosis. Testing for impotence may give clues as to the cause, but we cannot rule out impotence by doing a test in a patient who cannot function sexually!

This is not to say that establishment of a valid diagnostic marker would not be a major advance in our understanding of IC. Just as with phenotyping, it will be important largely to the extent that it can predict prognosis in a given group of patients, predict response to therapy in a given group of patients, and/or distinguish between BPS/IC and another possible cause of the symptom complex that has been diagnosed. Ultimately, marker identification may enable us to stratify patients with the symptom complex in such a way that treatments will be specific to the specific cause (i.e., disease) the patient has. As various causes are identifiable, the diagnosis of BPS may itself become a rarity, much like what has happened to “acute urethral syndrome” (Stamm et al, 1980).

In just such an effort, numerous investigators have looked at the mast cell as a possible diagnostic marker for IC. The current standard involves detrusor muscle biopsy specimens examined with tryptase staining of 3- μ m thick sections, with every seventh section used for quantification (Larsen et al, 2008). Twenty-seven mast cells per cubic millimeter is considered indicative of mastocytosis. The results in the past have been very contradictory, and at this time, in terms of the use of mast cell criteria in diagnosis, the issue remains moot (Kastrup et al, 1983; Feltis et al, 1987; Holm-Bentzen et al, 1987a; Lynes et al, 1987; Hanno et al, 1990; Christmas and Rode, 1991; Moore et al, 1992; Dundore et al, 1996; Hofmeister et al, 1997). Methylhistamine, a histamine metabolite found in the urine and thought to reflect mast cell activation, was not associated

with symptom scores, response to bladder distention, cystoscopic findings, or bladder biopsy features including mast cell determination by tryptase staining (Erickson et al, 2004).

Attempts have been made to look at other markers (Erickson, 2001), including eosinophil cationic protein (Lose et al, 1987), GAG excretion (Hurst et al, 1993), and urinary histamine and methylhistamine (El Mansoury et al, 1994). Proposals for measuring smooth muscle isoactin expression (Rivas et al, 1997) and urinary levels of neurotrophin-3, nerve growth factor, glial cell line-derived neurotrophic factor, and tryptase (Okragly et al, 1999) have been suggested. Low levels of GP51, a urinary glycoprotein with a molecular weight of 5 kDa, have been documented in IC patients compared with normal controls and patients with other urinary tract disease (Byrne et al, 1999). Cell cultures (Elgavish et al, 1997) have been proposed as a screening technique.

The measurement of elevated nitric oxide levels in air instilled and incubated in the bladder has been proposed for office screening (Lundberg et al, 1996; Ehrén et al, 1999). Increased levels of endogenously formed nitric oxide in patients with IC correspond to increased iNOS mRNA expression and protein levels in these patients. Furthermore, iNOS was found to be localized to the urothelium, but it was also found in macrophages in the bladder mucosa (Koskela et al, 2008). The simple technique allows for discrimination of ulcer from nonulcer disease (Logadottir et al, 2004) and may provide an objective measure of treatment response (Hoseini et al, 2004).

The urine APF identified by Keay (see earlier) may prove to be an accurate marker of BPS/IC if it can be confirmed by other centers and become a biochemical rather than biologic assay. It appears to have the highest sensitivity and specificity of the variety of possible markers tested and fits nicely into an etiologic schema (Keay et al, 2001a, 2001b; Erickson et al, 2002). It has also been shown to differentiate men with BPS/IC symptoms from controls and to differentiate men with bladder-associated pain and irritative voiding symptoms from those with pelvic or perineal pain alone and other nonspecific findings compatible with CPPS in men (CPPS III), previously referred to as *nonbacterial prostatitis* (Keay et al, 2004a). This question—whether CPPS and BPS/IC are two different disorders—will doubtless be the subject of future research and is an integral question that the NIDDK is hoping to answer with current research (www.mappnetwork.org). Data regarding the reproducibility of APF and any practical clinical uses are lacking.

Much work in markers is ongoing. Uroplakin III-delta 4 is a potential marker for identifying nonulcerative IC (Zeng et al, 2007). The feasibility of diagnosing IC in humans and domestic cats from the spectra of dried serum films (DSFs) using infrared microspectroscopy has been reported (Rubio-Diaz et al, 2009).

Potassium Chloride Test

Parsons has championed an intravesical KCl challenge, comparing the sensory nerve provocative ability of sodium versus potassium using a 0.4-M KCl solution. Pain and provocation of symptoms constitutes a positive test result. Whether the results indicate abnormal epithelial permeability in the subgroup of positive patients or hypersensitivity of the sensory nerves is unclear. Normal bladder epithelium can never be absolutely tight, and there is always some leak, however small (Hohlbrugger and Sant, 1997). The concentration of potassium used is 400 mEq/L, far exceeding the physiologic urinary concentrations of 20 to 80 mEq/L depending on dietary intake (Vander, 1995). Healthy controls can distinguish KCl from sodium chloride, although they don't experience severe pain (Roberto et al, 1997). The hope is that this test may stratify patients into those who will respond to certain treatments (perhaps those designed to fortify the GAG layer), but to date this information is lacking (Teichman and Nielsen-Omeis, 1999).

Used as a diagnostic test for IC, the KCl test is not valid (Chambers et al, 1999). The gold standard in defining BPS/IC for research purposes has been the NIDDK criteria. These criteria are recognized to constitute a set of patients that virtually all researchers

can agree have BPS/IC, though they are far too restrictive to be used in clinical practice (Hanno et al, 1999b). Thus, this group of patients should virtually all be positive if the KCl test is to have the sensitivity needed to aid in diagnosis. Up to 25% of patients meeting the NIDDK criteria will have a negative KCl test result (Parsons et al, 1998). In the group of patients in whom it should perform best, it is lacking in sensitivity.

When we look at the specificity side of the equation, in the universe of unselected persons, studies reported a 36% false-positive rate in asymptomatic men (Yilmaz et al, 2004) and a 33% positive rate in a fixed population of Turkish textile workers (Sahinkanat et al, 2008). In the patient population with confounding conditions for which we would want help in sorting out BPS/IC from other disorders, 25% of patients with overactive bladder test positive and virtually all patients with irritative symptoms from radiation cystitis and urinary tract infection test positive (Parsons et al, 1994b, 1998). The results with chronic prostatitis and CPPS in men are variable, but 50% to 84% of men have been reported to test positive (Parsons and Albo, 2002; Yilmaz et al, 2004; Parsons et al, 2005). In women with pelvic pain the results are similar (Parsons et al, 2002b), and based on these findings Parsons has expressed the view that BPS/IC may affect over 20% of the female population of the United States (Parsons et al, 2002a). Another way to interpret the findings would be that the KCl test is very nonspecific, missing

a significant number of BPS/IC patients and overdiagnosing much of the population.

Prospective and retrospective studies looking at the KCl test for diagnosis in patients with symptoms of BPS/IC have found no benefit of the test in comparison with standard techniques of diagnosis (Chambers et al, 1999; Gregoire et al, 2002; Kuo, 2003), and it is not useful for monitoring results of treatment (Sairanen et al, 2007). The development of a painless modification of the KCl test (Daha et al, 2003) using cystometric capacity and a 0.2-M solution may improve acceptability among patients, but further research is needed to determine what place, if any, this test will have in the diagnostic or treatment algorithm.

Confusable Diseases (Differential Diagnosis)

The diagnosis of BPS can be made on the basis of exclusion of confusable diseases and confirmed by the recognition of the presence of the specific combination of symptoms and signs of BPS. If the main urinary symptoms are not explained by a single diagnosis, the presence of a second diagnosis is possible. One must remember that BPS may occur together with confusable diseases such as chronic or remitting urinary infections or endometriosis. Table 14-3 summarizes confusable diseases related to BPS and their mode of exclusion based on aforementioned diagnostic

TABLE 14-3 Diseases That May Be Mistaken for Bladder Pain Syndrome

CONFUSABLE DISEASE	EXCLUDED OR DIAGNOSED BY
Carcinoma and carcinoma in situ	Cystoscopy and biopsy
Infection with: Common intestinal bacteria <i>Chlamydia trachomatis</i> , <i>Ureaplasma urealyticum</i> , <i>Mycoplasma hominis</i> , <i>Mycoplasma genitalium</i> , <i>Corynebacterium urealyticum</i> , <i>Candida</i> species, <i>Mycobacterium tuberculosis</i> Herpes simplex and human papillomavirus	Routine bacterial culture Special cultures Dipstick; if “sterile” pyuria, culture for <i>M. tuberculosis</i> Physical examination
Radiation	Medical history
Chemotherapy, including immunotherapy with cyclophosphamide	Medical history
Anti-inflammatory therapy with tiaprofenic acid	Medical history
Bladder neck obstruction and neurogenic outlet obstruction	Uroflowmetry and ultrasonography
Bladder stone	Imaging or cystoscopy
Lower ureteral stone	Medical history and/or hematuria; upper urinary tract imaging (CT or IVP)
Urethral diverticulum	Medical history and physical examination
Urogenital prolapse	Medical history and physical examination
Endometriosis	Medical history and physical examination
Vaginal candidiasis	Medical history and physical examination
Cervical, uterine, and ovarian cancer	Physical examination
Incomplete bladder emptying (retention)	Postvoid residual urine volume measured by ultrasound evaluation
Overactive bladder	Medical history and urodynamics
Prostate cancer	Physical examination and PSA test
Benign prostatic obstruction	Uroflowmetry and pressure-flow studies
Chronic bacterial prostatitis	Medical history, physical examination, culture
Chronic nonbacterial prostatitis	Medical history, physical examination, culture
Pudendal nerve entrapment	Medical history, physical examination; nerve block may prove diagnosis
Pelvic floor muscle-related pain	Medical history, physical examination

CT, computed tomography; IVP, intravenous pyelogram; PSA, prostate-specific antigen.

From van de Merwe JP, Nordling J, Bouchelouche P, et al. Diagnostic criteria, classification, and nomenclature for painful bladder syndrome/interstitial cystitis: an ESSIC proposal. *Eur Urol* 2008;53:60–7.

proposals and procedures as outlined by the ESSIC group (van de Merwe et al, 2008).

KEY POINTS: DIAGNOSIS

- BPS remains a diagnosis of exclusion in patients who meet the symptomatic criteria for diagnosis after confusable disorders have been ruled out.
- Cystoscopy with bladder distention under anesthesia aids in the diagnosis of a Hunner lesion but is not considered a prerequisite for beginning treatment.
- Cystoscopy and upper tract imaging are mandatory in patients with hematuria who have not been previously evaluated for this finding.
- Urodynamics are optional and usually reserved for complex cases. There are no commonly available laboratory markers that substantially contribute to diagnosis.

CLASSIFICATION

IC was originally described as a bladder disease with severe inflammation of the bladder wall described by Hunner as an ulcer (Hunner, 1915). The lesion is, however, not an ulcer, but a vulnus (weakness, vulnerability) that can ulcerate on distention, and the name of the bladder lesion has consequently been changed to *Hunner lesion* (van de Merwe et al, 2008). The finding of a Hunner lesion could therefore originally be regarded as a diagnostic criterion for IC. Messing and Stamey introduced glomerulations alone as another typical finding for IC, and this was included in the NIDDK criteria (Wein et al, 1990).

Magnus Fall proposed that patients with Hunner lesions (classic IC) and patients with glomerulations (non-Hunner type) represented two different subtypes (Fall et al, 1987). They may have different clinical pictures, different outcomes, and different responses to treatment (Peeker and Fall, 2002b). Patients with Hunner lesions were found to have a 5-fold to 20-fold increase in the chemokines CXCL-10 and CXCL-1, interleukin-6, and nerve growth factor when compared with BPS patients without Hunner lesions (Tyagi et al, 2012). Different expression patterns of the genes involved in proinflammatory reactions suggest distinct pathophysiologies for Hunner lesion patients compared with patients with BPS without Hunner lesions (Homma et al, 2013).

Thus, patients fulfilling the NIDDK criteria represent at least two (and possibly more) different patient populations. Moreover, up to 60% of patients clinically believed to have BPS by experienced clinicians do not fulfill the NIDDK criteria (Hanno et al, 1999b) and whether or not these patients are comparable to the patients fulfilling the NIDDK criteria is unknown. Finally, Japanese urologists consider that *interstitial cystitis* should be preserved as a disease name reserved for patients with urinary symptoms and cystoscopic findings of glomerulations or Hunner lesion as outlined in the NIDDK criteria (Homma, 2008).

In an attempt to unite these different philosophies into a coherent schema, ESSIC proposed a classification of BPS based on findings during CHD and morphologic findings in bladder biopsy specimens (van de Merwe et al, 2008) (see Table 14-1). The classification includes groups not having had CHD (group X) as well as groups not having had morphologic investigation of bladder biopsy specimens (group XX). By using this classification, future researchers will be able to identify whether findings of glomerulations and/or Hunner lesion as well as morphologic changes in bladder biopsy specimens do have significant importance for disease prognosis and/or treatment outcome (Geurts et al, 2011).

TREATMENT

Conservative Therapies

Once the diagnosis has been made, one must decide whether to institute therapy or employ a policy of conservative watchful

waiting. If the patient has not had an empirical course of antibiotics for their symptoms by the time the BPS/IC diagnosis is made, such a trial is reasonable. Doxycycline has been reported efficacious in a Swiss study (Burkhard et al, 2004). Further attempts to alleviate symptoms with antibiotics are unlikely to be worthwhile and are not recommended in the absence of positive cultures. **Stress reduction, exercise, warm tub baths, and efforts by the patient to maintain a normal lifestyle all contribute to overall quality of life (Whitmore, 1994).** In a large patient survey, dietary changes, application of heat or cold, and stress reduction all had positive response rates in over 80% of responders (O'Hare et al, 2013). In a controlled study of 45 PBS/IC patients and 31 healthy controls, higher levels of stress were related to greater pain and urgency in patients with IC but not in the control group (Rothrock et al, 2001). Maladaptive strategies for coping with stress may adversely affect symptoms (Rothrock et al, 2003).

Biofeedback, soft-tissue massage, and other physical therapies may aid in muscle relaxation of the pelvic floor (Mendelowitz et al, 1997; Meadows, 1999; Holzberg et al, 2001; Lukban, et al, 2001; Markwell, 2001). This is a reasonable intervention, given the strong association of pelvic floor dysfunction and BPS/IC (Peters et al, 2007a; Bassaly et al, 2011). A preliminary NIDDK trial demonstrated the feasibility of such a study and strongly suggested the efficacy of physical therapy when compared with global therapeutic massage (FitzGerald et al, 2009). This was confirmed in a randomized controlled trial comparing 10 scheduled treatments of myofascial physical therapy versus global therapeutic massage at 11 North American clinical centers. The Global Response Assessment (GRA) response rate was 26% in the global therapeutic massage group and 59% in the myofascial physical therapy group ($P = .0012$) (FitzGerald et al, 2012).

Mendelowitz and Moldwin had a 69% success rate in 16 patients treated with electromyographic biofeedback (Mendelowitz et al, 1997), but treatment response did not correlate to changes in muscle identification, and the placebo effect may have been considerable. **Acupuncture** has been used for BPS/IC and many other chronic pain syndromes. There is **limited evidence that it is more effective than nontreatment for chronic pain** and inconclusive evidence that acupuncture is more effective than placebo, sham acupuncture, or standard care (Ezzo et al, 2000). **BPS/IC results with acupuncture have been disappointing (Geirsson et al, 1993).**

Diet

Elaborate dietary restrictions are unsupported by any literature, but many patients do find their symptoms are adversely affected by specific foods and would do well to avoid them (Koziol et al, 1993; Koziol, 1994). Often these include caffeine, alcohol, artificial sweeteners, hot peppers, and beverages that might acidify the urine, such as cranberry juice (Shorter et al, 2007). Several acid-sensing ion channel subunits are expressed in human bladder, and the upregulation of some of these channels in BPS/IC patients suggests involvement in increased pain and hyperalgesia (Sanchez-Freire et al, 2011). Anecdotal association of IC with many foods has spawned the recommendation of various "interstitial cystitis diets" with little in the way of objective, scientific basis (Box 14-7). The only placebo-controlled dietary study, although small, failed to demonstrate a relationship between diet and symptoms (Fisher et al, 1993). Bade and colleagues found that IC patients tend to have a healthier diet than the general population but could discern no rationale for dietary or fluid intake change other than decreasing caffeine intake (Bade et al, 1997b). Nguan and coworkers performed a prospective, double-blind, crossover study consisting of crossover instillations of urine at physiologic pH (5.0) and neutral buffered pH (7.5) (Nguan et al, 2005). There was no statistically significant difference in subjective pain scores, suggesting that adjusting urine pH with diet or dietary supplements may have little influence on symptomatology. Orange and grapefruit juices, rich in potassium and citrate, tend to increase urinary pH (Wabner and Pak, 1993) but are avoided by many IC patients based on "IC diet" recommendations and their personal experience with food-related

flares. Alkalinizing the urine may be worth trying, but supporting studies are lacking. Some patients have had benefit with calcium glycerophosphate, an over-the-counter food acid-reducing agent (Hill et al, 2008; O'Hare et al, 2013), but supporting controlled trials are lacking. A controlled method to determine dietary sensitivities, such as an elimination diet, may play an important role in patient management (Friedlander et al, 2012).

In a large National Institutes of Health study, patients with newly diagnosed BPS/IC were treated with a focus on four targeted areas: (1) controlling or managing symptoms, (2) controlling fluid intake, (3) changing the diet to one that might improve symptoms, and (4) bladder training and urge suppression. A behavioral approach to stress and pain management was also used to help patients learn skills to reduce stress in their lives. Of 135 patients randomized to this approach without additional medication, 45% were moderately or markedly improved at the 12-week end point (Foster et al, 2010). In another trial, hydrodistention followed by bladder training produced a statistically significant better response at 24 weeks post-procedure than hydrodistention alone (Hsieh et al, 2012).

Unfortunately, education and self-help are often not sufficient, and most patients will require one or more of a variety of therapies.

Oral Therapies (Table 14-4)**Amitriptyline**

Amitriptyline, a tricyclic antidepressant, has become a staple of oral treatment for BPS/IC. The tricyclics possess varying degrees of at least three major pharmacologic actions: (1) They have central and peripheral anticholinergic actions at some but not all sites, (2) they block the active transport system in the presynaptic nerve ending that is responsible for the reuptake of the released amine neurotransmitters serotonin and noradrenaline, and (3) they are sedatives, an action that occurs presumably on a central basis but perhaps is related to their antihistaminic properties. Amitriptyline, in fact, is one of the most potent tricyclic antidepressants in terms of blocking H₁-histaminergic receptors (Baldessarini et al, 1985).

There is also evidence that they desensitize α_2 receptors on central noradrenergic neurons. Paradoxically, they also have been shown to block α -adrenergic receptors and serotonin receptors. Theoretically, tricyclic agents have actions that might tend to stimulate predominantly β -adrenergic receptors in bladder body smooth musculature, an action that would further facilitate urine storage by decreasing the excitability of smooth muscle in that area (Barrett et al, 1987).

Hanno and Wein first reported a therapeutic response in IC after noting a "serendipitous" response to amitriptyline in one of their patients concurrently being treated for depression (Hanno and Wein, 1987). The following year, a similar report appeared relating a response to desipramine hydrochloride (Renshaw, 1988). Reasoning that a drug used successfully at relatively low doses for many types of chronic pain syndromes, that would also have anticholinergic properties, β -adrenergic bladder effects, sedative characteristics, and strong H₁-antihistaminic activity, would seem to be ideal for IC, the first clinical trial was carried out with promising results (Hanno et al, 1989). A subsequent follow-up study (Hanno, 1994a) reported that in 28 of 43 patients who could tolerate therapy for at least a 3-week trial at a dose of 25 mg at bedtime gradually increasing to 75 mg at bedtime over 2 weeks, 18 had total remission of symptoms with a mean follow-up of 14.4 months, 5 dropped out because of side effects, and 5 derived no clinical benefit. Benefits were apparent within 4 weeks. In all patients, hydrodistention and intravesical DMSO therapy had failed. Sedation was the main side effect. Kirkemo and colleagues treated 30 patients and had a 90% subjective improvement rate at 8 weeks (Kirkemo et al, 1990). Both studies noted that patients with bladder capacities over 450 to 600 mL under anesthesia seemed to have the best results. Another uncontrolled study of 11 patients with urinary frequency and pelvic pain (Pranikoff and Constantino, 1998) related success in 9 of the patients, with 5 reporting complete resolution of symptoms and 4 significant relief. Two patients could not tolerate the medication. In a 4-month intent-to-treat placebo-controlled double-blind trial of 50 patients, 63% on amitriptyline at doses of 25 to 75 mg (dose as tolerated) before bed reported good or excellent satisfaction versus

4% on placebo (van Ophoven et al, 2004a). At 19-month follow-up there was little tachyphylaxis, and good response rates were observed in the entire spectrum of BPS/IC symptoms (van Ophoven and Hertle, 2005).

The large, double-blind, randomized controlled trial by the NIDDK comparing education and behavioral modification with and without oral amitriptyline showed a 55% response in the arm that included both medication and conservative therapy compared with a 45% response to education and behavioral

therapy alone (Foster et al, 2010). The difference was not statistically significant. However, if only patients who could tolerate 25 mg or more of medication or placebo are included, the success compared with conservative therapy alone was 73% compared with 53% at 12 weeks. Frequency and O’Leary-Sant symptom and problem scores also showed significant improvement. Thus, on an intent-to-treat basis, there was not significant benefit from amitriptyline, but in the 62% of patients who could tolerate these relatively low doses of drug, the benefits appear substantial (Yang et al, 2014). Patients should be cautioned about fatigue, constipation, dry mouth, increased appetite, and dizziness. Slowly titrating the dose on a weekly basis, beginning at 10 mg before bed and increasing by 10 mg weekly to a maximum tolerated dose of 50 mg before bed seems to minimize side effects. Amitriptyline appears to have efficacy that is unrelated to the presence or absence of a Hunner lesion, and cystoscopy shows no predictive value for treatment outcome (Sun et al, 2014). It may also be beneficial in treating the vulvar pain syndrome that sometimes accompanies BPS (Ventolini, 2013).

Amitriptyline has proven analgesic efficacy with a median preferred dose of 50 mg in a range of 25 to 150 mg daily. This range is lower than traditional doses for depression of 150 to 300 mg. The speed of onset of effect is much faster (1 to 7 days) than reported in depression, and the analgesic effect is distinct from any effect on mood (McQuay and Moore, 1997). Tricyclic antidepressants are contraindicated in patients with long QT syndrome or significant conduction system disease (bifascicular or trifascicular block) after recent myocardial infarction (within 6 months), unstable angina, congestive heart failure, frequent premature ventricular contractions, or a history of sustained ventricular arrhythmias. They should be used with caution in patients with orthostatic hypotension (Low and Dotson, 1998). Doses greater than 100 mg are associated with increased relative risk of sudden cardiac death (Ray et al, 2004).

Other Antidepressants

Other tricyclic antidepressants have been used for BPS. One trial employed the combination of doxepin and piroxicam, a cyclooxygenase-2 (COX-2) inhibitor. Twenty-six of 32 patients (81%) experienced remission of symptoms (Wammack et al, 2002). Another study reported satisfactory outcome with desipramine (Renshaw, 1988). The safety and efficacy of duloxetine, a serotonin and norepinephrine reuptake inhibitor, for BPS/IC was assessed in an observational study of 48 women (van Ophoven and Hertle, 2007). Patients were prospectively treated for 2 months after an uptitration protocol to the target dose of 40 mg duloxetine twice daily. Five patients were identified as responders and 17 patients dropped out because of side effects including nausea in all 17 patients. No severe adverse events were reported. In the 5 responders, the 40-mg twice daily dose was required for efficacy to be seen. Overall, duloxetine did not result in clinically meaningful improvement of symptoms.

Antihistamines

The use of antihistamines goes back to the late 1950s and stems from work by Simmons, who postulated that the local release of histamine may be responsible for or may accompany the development of IC (Simmons, 1961). He reported on 6 patients treated with pyribenzamine. The results were far from dramatic, with only half the patients showing some response. The therapy is notable for this disease in that it was very logically conceived. It has been Theoharides who has spearheaded mast cell research in this field and been a major modern proponent of antihistamine therapy (Theoharides, 1994). He has used the unique piperazine H₁-receptor antagonist hydroxyzine, a first-generation antihistamine (Simons, 2004), which can block neuronal activation of mast cells (Minogianis et al, 1998). In 40 patients treated with 25 mg before bed increasing over 2 weeks (if sedation was not a problem) to 50 mg at night and 25 mg in the morning, virtually every symptom

evaluated improved by 30%. Only 3 patients had absolutely no response. As with many IC drug reports, these responses were evaluated subjectively and without blinding or placebo control. A subsequent study suggested improved efficacy in patients with documented allergies and/or evidence of bladder mast cell activation (Theoharides et al, 1997; Theoharides and Sant, 1997). No significant response to hydroxyzine was found in an NIDDK placebo-controlled trial (Sant et al, 2003).

Why an H₂-antagonist would be effective is unclear, but uncontrolled studies show improvement of symptoms in two thirds of patients taking cimetidine in divided doses totaling 600 mg (Seshadri et al, 1994; Lewi, 1996). It proved effective in a double-blind, placebo-controlled trial (Thilagarajah et al, 2001), but histologic studies show the bladder mucosa to be unchanged before and after treatment, and the mechanism of any efficacy remains unexplained (Dasgupta et al, 2001). Cimetidine is a common treatment in the United Kingdom, where over a third of patients reported having used it (Tincello and Walker, 2005).

Sodium Pentosan Polysulfate

Parson's suggestion that a defect in the epithelial permeability barrier, the GAG layer, contributes to the pathogenesis of IC has led to an attempt to correct such a defect with the synthetic sulfated polysaccharide sodium pentosan polysulfate (PPS), a heparin analogue available in an oral formulation, 3% to 6% of which is excreted into the urine (Barrington and Stephenson, 1997). It is sold under the trade name Elmiron. Study findings have been contradictory.

Fritjofsson treated 87 patients in an open multicenter trial in Sweden and Finland (Fritjofsson et al, 1987). Bladder volume with and without anesthesia was unchanged. Relief of pain was complete in 35% and partial in 23% of patients. Daytime frequency decreased from 16.5 to 13 and nocturia decreased from 4.5 to 3.5. Mean voided volumes increased by almost a tablespoon in the nonulcer group. Holm-Bentzen studied 115 patients in a double-blind, placebo-controlled trial (Holm-Bentzen et al, 1987b). Symptoms, urodynamic parameters, cystoscopic appearance, and mast cell counts were unchanged after 4 months. Bladder capacity under anesthesia increased significantly in the group with mastocytosis, but this had no bearing on symptoms or awake capacity.

Parsons had a more encouraging initial experience (Parsons et al, 1983), and subsequently the results of two placebo-controlled multicenter trials in the United States were published (Mulholland et al, 1990; Parsons et al, 1993). In the initial study, overall improvement of more than 25% was reported by 28% of the PPS-treated group versus 13% of the placebo group. In the latter study the respective figures were 32% on drug versus 16% on placebo. Average voided volume on PPS increased by 20 mL. No other objective improvements were documented. An NIDDK 2 × 2 factorial study to evaluate PPS and hydroxyzine looked at each drug used alone and in combination and compared results with a placebo group (Sant et al, 2003). Patients were treated for 6 months. No statistically significant response to either medication was documented. No significant trend was seen in the PPS treatment groups (34%) compared with non-PPS groups (18%). Of the 29 patients on PPS alone, 28% had a global response (the primary end point) of moderate or marked improvement versus 13% on placebo, a number remarkably similar to the results in the 3-month pivotal trials, although not reaching statistical significance in the 6-month study. A subsequent industry-sponsored trial showed no dose-related efficacy response in the range of 300 to 900 mg daily; however, adverse events were dose related (Nickel et al, 2005a). Another 6-month trial that compared PPS with cyclosporine A yielded a 19% response rate for PPS compared with a 75% global response to cyclosporine A (Sairanen et al, 2005).

Long-term experience with PPS in uncontrolled studies is consistent with efficacy in a subset of patients (Al-Zahrani and Gajewski 2011) that may drop below 30% of those initially treated (Jepsen et al, 1998). Tachyphylaxis seems to be uncommon in responders. A phase 4 study mandated by the U.S. Food and

Drug Administration (FDA) and initiated in July 2004 was terminated in January 2011. It evaluated the safety and efficacy of PPS, comparing 100 mg once a day, 100 mg three times a day, and placebo for 24 weeks in 66 study locations in 369 patients. The study was terminated when interim analysis showed that study continuation was futile and the drug was ineffective (<http://clinicaltrials.gov/ct2/show/results/NCT00086684?term=elmiron&rank=1>).

Adverse events with PPS occurred in less than 4% of patients at the dose of 100 mg three times daily (Hanno, 1997) and included reversible alopecia, diarrhea, nausea, and rash. Rare bleeding problems have been reported (Rice et al, 1998). It promotes cellular proliferation in vitro in the MCF-7 breast cancer cell line, and caution has been suggested in prescribing it in groups at high risk for breast cancer and premenopausal females (Zaslau et al, 2004). A 3- to 6-month treatment trial is usually required to see symptom improvement. In a small trial, PPS has shown efficacy when administered intravesically (Bade et al, 1997a). It may be of value in the management of radiation cystitis (Parsons, 1986; Hampson and Woodhouse, 1994) and cyclophosphamide cystitis (Toren and Norman, 2005), but its value in the treatment of BPS/IC seems marginal.

Immunomodulator Drugs

Cyclosporine. Cyclosporine, a widely used immunosuppressive drug in organ transplantation, was the subject of a novel BPS trial (Forsell et al, 1996). Eleven patients received cyclosporine for 3 to 6 months at an initial dose of 2.5 to 5 mg/kg daily and a maintenance dose of 1.5 to 3 mg/kg daily. Micturition frequency decreased, and mean and maximum voided volumes increased significantly. Bladder pain decreased or disappeared in 10 patients. After cessation of treatment, symptoms recurred in the majority of patients.

In a longer-term follow-up study, 20 of 23 refractory IC patients on cyclosporine therapy followed for a mean of 60.8 months became free of bladder pain. Bladder capacity more than doubled. Eleven patients subsequently stopped therapy, and in 9, symptoms recurred within months but responded to reinitiating cyclosporine (Sairanen et al, 2004). Sairanen and colleagues further found that cyclosporine A was far superior to sodium PPS in all clinical outcome parameters measured at 6 months (Sairanen et al, 2005). Patients who responded to cyclosporine A had a significant reduction of urinary levels of EGF (Sairanen et al, 2008). Data from three centers in the United States reported success in 23 of 34 patients with Hunner lesions and 3 of 10 patients without Hunner lesions (Forrest et al, 2012). A 3- to 4-month trial was suggested to gauge treatment success. Measurement of luminal nitric oxide has correlated lower levels with treatment response to cyclosporine (Ehrén et al, 2013). A case report highlighted success in a patient with primary SS and BPS (Emmungil et al, 2012).

Suplatast Tosilate. Suplatast tosilate (IPD-1151T) is an immunoregulator that selectively suppresses IgE production and eosinophilia via suppression of helper T cells that produce IL-4 and IL-5. It is used in Japan to treat allergic disorders including asthma, atopic dermatitis, and rhinitis. Ueda and colleagues reported a small study in 14 women with IC (Ueda, 2000). Treatment for 1 year resulted in a significantly increased bladder capacity and decreased urinary urgency, frequency, and lower abdominal pain in 10 women. Concomitant changes occurred in blood and urine markers, suggesting an immune system response. Larger, multicenter, randomized controlled trials in the United States and Japan have not led to the governmental approval of the BPS/IC indication or the introduction of the drug into the United States.

Azathioprine and Chloroquine Derivatives. In a single report in 1976, Oravisto and colleagues used azathioprine or chloroquine derivatives for BPS patients not responding to other treatments (Oravisto and Alfthan, 1976). About 50% of patients responded.

Mycophenolate Mofetil. In an aborted multicenter randomized placebo-controlled NIDDK trial, mycophenolate mofetil (CellCept) 1 to 2 g daily in divided doses failed to show efficacy in the treatment of symptoms of refractory BPS/IC. The trial, which included

59 patients randomized 2:1 to the active arm, was halted when the FDA issued a new black box warning for the drug (*miscarriage and congenital malformations have been associated with its use*), and an **interim analysis showed no benefit** (Yang et al, 2011).

Adalimumab. A randomized double-blind placebo-controlled trial of this TNF-inhibiting anti-inflammatory agent failed to demonstrate positive proof of concept for this drug, which is approved for use in the treatment of rheumatoid, psoriatic, and other types of arthritis; plaque psoriasis; Crohn disease; and ulcerative colitis (Bosch, 2014).

Miscellaneous Agents

L-Arginine. Foster and Weiss were the original proponents of L-arginine in the therapy of IC (Foster et al, 1997). Eight patients with IC were given 500 mg of L-arginine three times daily. After 1 month, urinary NOS activity increased 8-fold and 7 of the 8 patients noticed improvement in symptoms. An open-label study of 11 patients showed improvement in all 10 of the patients who remained on L-arginine for 6 months (Smith et al, 1997).

An open-label study of 9 women in Sweden failed to find any change in symptom scores or in nitric oxide production in the bladder (Ehrén et al, 1998). A placebo-controlled randomized trial of 53 BPS/IC patients could find no difference on an intention-to-treat analysis between drug- and placebo-treated patients (Korting et al, 1999). A smaller randomized placebo-controlled crossover trial of 16 BPS patients found no clinically significant improvement with L-arginine and concluded that it could not be recommended for IC treatment (Cartledge et al, 2000).

The body of evidence does not support the use of L-arginine for the relief of symptoms of IC.

Quercetin. Quercetin, a bioflavonoid available in many over-the-counter products, may have the anti-inflammatory effects of other members of this class of compounds found in fruits, vegetables, and some spices. Katske and colleagues administered 500 mg twice daily to 22 BPS patients for 4 weeks (Katske et al, 2001). All but 1 patient had some improvement in the O'Leary-Sant symptom and problem scores as well as in a global assessment score. Further larger studies with placebo controls are necessary to determine efficacy.

Antibiotics. Warren and colleagues (2000) randomized 50 patients to receive 18 weeks of placebo or antibiotics including rifampin plus a sequence of doxycycline, erythromycin, metronidazole, clindamycin, amoxicillin, and ciprofloxacin for 3 weeks each. Intent-to-treat analysis demonstrated that 12 of 25 patients in the antibiotic and 6 of 25 patients in the placebo group reported overall improvement, whereas 10 and 5, respectively, noticed improvement in pain and urgency. The study was complicated by the fact that 16 of the patients in the antibiotic group underwent new BPS therapy during the study, as did 13 of the placebo patients. There was no statistical significance reached. What was statistically significant was the occurrence of adverse events in 80% of participants who received antibiotics compared with 40% in the placebo group. Nausea and/or vomiting and diarrhea were the predominant side effects. Most patients on antibiotics correctly guessed what treatment arm they were in, and those who guessed correctly were significantly more likely to note improvement after the study. No duration in improvement after completion of the trial of antibiotics was reported.

Burkhard and colleagues recorded a 71% success rate in 103 women with a history of urinary urgency and frequency and chronic urethral and/or pelvic pain often associated with dyspareunia and/or a history of recurrent urinary tract infection (Burkhard et al, 2004). This was a large, inclusive group and one that is probably broader than the BPS on which we are focusing. Nevertheless, Burkhard recommended empirical doxycycline in this group. The overwhelming majority of BPS patients have been treated with empirical antibiotics before diagnosis.

At this time there is no evidence to suggest that antibiotics have a place in the therapy of BPS in the absence of a culture-documented infection (Maskell, 1995). Nevertheless, it would not

be unreasonable to treat patients with *one* empirical course of antibiotic, if they have never been on an antibiotic for their urinary symptoms.

Methotrexate. Low-dose oral methotrexate significantly improved bladder pain in four of nine women with BPS but did not change urinary frequency, maximum voided volume, or mean voided volume (Moran et al, 1999). No placebo-controlled RCT has been done with this agent.

Montelukast. Mast cell triggering releases two types of proinflammatory mediators, including granule stored preformed types such as heparin and histamine and newly synthesized prostaglandins and leukotrienes B₄ and C₄. Classic antagonists, such as montelukast, zafirlukast, and pranlukast, block cysteinyl leukotriene-1 receptors. In a pilot study (Bouchelouche et al, 2001b), 10 women with IC and detrusor mastocytosis received 10 mg of montelukast daily for 3 months. Frequency, nocturia, and pain improved dramatically in 4 of the patients. Further study would seem to be warranted, especially in patients with detrusor mastocytosis, defined as more than 28/mm² (Traut et al, 2011).

Nifedipine. The calcium channel antagonist nifedipine inhibits smooth muscle contraction and cell-mediated immunity. In a pilot study (Fleischmann, 1994), 30 mg of an extended-release preparation was administered to 10 female patients and titrated to 60 mg daily in 4 of the patients who did not get symptom relief. Within 4 months, 5 patients showed at least a 50% decrease in symptom scores, and 3 of the 5 were asymptomatic. No further studies have been reported.

Misoprostol. The oral prostaglandin analogue misoprostol was studied in 25 patients at a dose of 600 µg daily (Kelly et al, 1998). At 3 months 14 patients were significantly improved, and at 6 months 12 patients still had a response. A cytoprotective action in the urinary bladder was postulated.

Dextroamphetamine. A single anecdotal series of six patients reported benefit from use of 30 mg of dextroamphetamine sulfate daily, with return of symptoms on discontinuation of medication (Check et al, 2013).

Phosphodiesterase Inhibitors. The use of phosphodiesterase (PDE) inhibitors for BPS has long been considered. PDE type 5 (PDE5) inhibitors are hypothesized to relax smooth muscle or structures involved in afferent signaling and suppress smooth muscle spontaneous activity (Truss et al, 2001; Hanna-Mitchell and Birdier, 2011; Chen et al, 2014a). Trials using them for BPS are underway.

Analgesics

The long-term, appropriate use of pain medications forms an integral part of the treatment of a chronic pain condition such as IC. Most patients can be helped markedly with medical pain management using pain medications commonly used for chronic neuropathic pain syndromes including antidepressants, anticonvulsants, and opioids (Wesselmann et al, 1997). Many nonopioid analgesics including acetaminophen and the nonsteroidal anti-inflammatory drugs (NSAIDs) and even antispasmodic agents (Rumman, 1994) have a place in therapy along with agents designed to specifically treat the disorder itself.

Studies on the use of analgesics for BPS are sparse, and most data have been inferred from non-BPS types of pain and expert opinion. Health professionals should ask about pain, and the patient's self-report should be the primary source of assessment. Clinicians should assess pain with easily administered rating scales and should document the efficacy of pain relief at regular intervals after starting or changing treatment.

Unlike opioids, with increasing doses acetaminophen, aspirin, and the other NSAIDs all reach a ceiling for their maximum analgesic effect (Drugs for pain, 1998). Gabapentin, introduced in 1994 as an anticonvulsant, has found efficacy in neuropathic pain disorders including diabetic neuropathy (Backonja et al, 1998) and postherpetic neuralgia (Rowbotham et al, 1998). It demonstrates synergism with morphine in neuropathic pain (Gilon et al, 2005). It may give some benefit in CPPS and BPS/IC (Sasaki et al, 2001). Pregabalin is also reported to be effective

for neuropathic pain and the pain of fibromyalgia (Freynhagen et al, 2005; Arnold et al, 2008).

With the results of major surgery anything but certain, the use of long-term opioid therapy in the patient in whom more conservative therapies have failed may also be considered (Box 14-8). Opiates are seldom the first choice of analgesics in chronic pain states, but they should not be withheld if less powerful analgesics have failed (Portenoy et al, 1997; Bennett, 1999). This is a difficult decision that requires much thought and discussion between patient and urologist, and involvement of a pain specialist is indicated. A single practitioner has to take responsibility for pain treatment and write all prescriptions for pain medications (Brookoff and Sant, 1997). Opioids are effective for most forms of moderate and severe pain and have no ceiling effect other than that imposed by adverse effects. The common side effects include sedation, nausea, mild confusion, and pruritus. In general, these are transient and easily managed. Respiratory depression is extremely rare if they are used as prescribed. Constipation is common and a mild laxative is typically necessary. The major impediment to the proper use of these drugs when they are prescribed for long-term nonmalignant

BOX 14-8 General Guidelines for the Use of Opioids in Chronic or Nonacute Urogenital Pain

1. All other reasonable treatments must have been tried and failed.
2. The decision to instigate long-term opioid therapy should be made by an appropriately trained specialist in consultation with another physician (preferably the patient's family doctor).
3. When there is a history or suspicion of drug abuse, a psychiatrist or psychologist with an interest in pain management and drug addiction should be involved.
4. The dose required needs to be calculated by careful titration.
5. The patient should be made aware of (and possibly give written consent regarding) the following:
 - a. Opioids are strong drugs and associated with addiction and dependency.
 - b. Opioids will normally be prescribed from only one source.
 - c. The drugs will be prescribed for fixed periods of time and a new prescription will not be available until the end of that period.
 - d. The patient will be subjected to spot urine and possibly blood checks to ensure that the drug is being taken as prescribed and that nonprescribed drugs are not being taken.
 - e. Inappropriate aggressive behavior associated with demanding the drug will not be accepted.
 - f. Hospital specialist review will normally occur at least once a year.
 - g. The patient may be requested to attend a psychiatric or psychological review.

Failure to comply with the above may result in the patient being referred to a drug dependency agency and the use of therapeutic, analgesic opioids being stopped.
6. Morphine is the first-line drug, unless there are contraindications to morphine or special indications for another drug. The drug should be prescribed in a slow-release or modified-release form. Short-acting preparations are undesirable and should be avoided where possible. Parenteral administration is undesirable and should be avoided when possible.

From Fall M, Baranowski A, Elneil S, et al. Guidelines on chronic pelvic pain. European Association of Urology; 2008. p. 1–99. www.uroweb.org/professional-resources/guidelines/.

pain is the fear of addiction. Studies suggest the risk is low (Gourlay, 1994). The long-acting narcotic formulations that result in steady levels of drug over many hours are preferable.

Chronic pain patients often receive inadequate doses of short-acting pain medications, which put them on cycles of short-term relief, anxiety, and pain. It leads to doctor-shopping and drug-seeking behavior confused by physicians with drug addiction. Although physical dependence on opioids will be unavoidable, physical addiction, a chronic disorder characterized by the compulsive use of a substance resulting in physical, psychological, or social harm to the user and the continued use despite that harm, is rare. Chronic opioid therapy can be considered in carefully selected patients. It is best administered in a pain clinic setting and necessitates frequent reassessment by both patient and physician (Portenoy and Foley, 1986).

KEY POINTS: ORAL THERAPIES

- Few of the oral therapies commonly used for the treatment of BPS have unequivocal evidence of efficacy in large, multicenter, randomized controlled clinical trials.
- There is little evidence that any of these therapies change the natural history of the disease, although many seem effective in individual patients.

Intravesical Therapies (see Table 14-4)

The use of silver nitrate and Clorpectin is described on the Expert Consult website. 

Dimethyl Sulfoxide

A mainstay of the treatment of BPS is the intravesical instillation of 50% DMSO (Sant, 1987). It is sometimes administered in a solution with sodium bicarbonate, heparin, and/or steroid, but its only FDA-approved use is as a stand-alone treatment (Stav et al, 2012; Gafni-Kane et al, 2013). DMSO is a byproduct of the wood pulp industry and a derivative of lignin. It has exceptional solvent properties and is freely miscible with water, lipids, and organic agents. One must be cognizant of systemic absorption of coadministered agents. Pharmacologic properties include membrane penetration, enhanced drug absorption, anti-inflammatory action (Kim et al, 2011), analgesic effects, collagen dissolution, muscle relaxation, and mast cell histamine release. In vitro effects on bladder function belie its positive effects in vivo (Freedman et al, 1989), where histamine release has not been demonstrated after treatment (Stout et al, 1995). It has been suggested that DMSO actually desensitizes nociceptive pathways in the lower urinary tract (Birder et al, 1997). Tests for DMSO for treatment of human illness began in the 1960s in the areas of musculoskeletal inflammation and the cutaneous manifestations of scleroderma.

Stewart and colleagues are credited for popularizing intravesical DMSO for BPS/IC (Stewart et al, 1967). In the mid 1960s he applied it to the skin over the suprapubic area in a group of patients refractory to conventional forms of therapy. Results were poor, but intravesical delivery of 50 mL of a 50% solution instilled for 15 minutes by catheter and repeated at intervals of 2 to 4 weeks showed positive effects lasting 2 to 12 months in six of eight patients. The absence of side effects, other than a garlic-like odor on the breath, and the lack of a need for inpatient administration were significant breakthroughs over previous treatments. Further reports by this group confirmed safety and efficacy (Stewart et al, 1971, 1972; Stewart and Shirley, 1976; Shirley et al, 1978) with symptom-free intervals of 1 to 3 months in 73% of patients. Ek reported a 70% success rate but found that most patients ultimately required retreatment or further therapy with other modalities (Ek et al, 1978). Prospective series of Fowler (Fowler, 1981) and Barker and colleagues (Barker et al,

Silver Nitrate

Although the evidence base for treating BPS/IC using intravesical preparations is limited and the potential for meta-analysis reduced by variation in the outcome measures used (Dawson and Jamison, 2007), intravesical lavage with one of a variety of preparations has remained a mainstay of treatment in the therapeutic armamentarium of BPS. Perhaps the oldest of the intravesical therapies is silver nitrate. The use of silver nitrate has been attributed to Mercier (Pool and Rives, 1944) who reported in 1855 that excellent results with bladder instillations had been obtained in patients with symptoms compatible with IC. Dodson advocated the use of solutions of silver nitrate in increasing strengths as the treatment of choice for this condition (Dodson, 1926). Pool and Rives (1944) reported on 74 patients with IC treated with intravesical silver nitrate. The treatment was carried out as follows:

A urethral catheter is inserted and the contents of the bladder are evacuated. The bladder is then irrigated with a saturated solution of boric acid. Then 30 to 60 cc of a 1:5000 solution of silver nitrate is instilled into the bladder and permitted to remain there for 3 or 4 minutes if it does not cause intolerable irritation. At the end of this period the solution is permitted to run out through the catheter, which is then withdrawn. The patient usually experiences some dysuria and vesical irritability for 2 or 3 hours. Treatments are repeated every other day. At subsequent treatments, the concentration of silver nitrate in the solution is increased to 1:2500, 1:1000, 1:750, 1:500, 1:400, 1:200, and finally 1:100. If at any time the reaction is too severe, the concentration is increased more slowly.

Although the initial treatments are performed with the patient under general anesthesia, later treatments are given on an outpatient basis. Ureteral reflux would be a contraindication, and it goes without saying that bladder biopsy would be contraindicated just before instillation for fear of extravasation. Twenty-three years later, Pool wrote that he still considered this treatment regimen the most efficacious form of treatment (Pool, 1967). Pool reported excellent results in 70% of patients with a mean response of 7.6 months. Burford reported a 14% cure rate and 79% improved figure (Burford and Burford, 1958). DeJuana had a 50% response rate in 102 patients (DeJuana and Everett, 1977).

Although silver nitrate is not used in the current treatment of BPS, an animal study showing that intravesical administration of nanocrystalline silver (1%) decreased urine histamine, bladder TNF- α , and mast cell activation in an experimental inflammation

model without any toxic effect, may restimulate interest in silver compounds (Boucher et al, 2008).

Clorpactin

O'Connor reported on the use of intravesical Clorpactin WCS 90 (O'Connor, 1955). *Clorpactin* is a term for closely related, highly reactive chemical compositions having a modified derivative of hypochlorous acid in a buffered base. Its activity is dependent on the liberation of hypochlorous acid and its resulting oxidizing effects, wetting and penetrating properties, and detergency. Wishard treated 20 patients with 0.2% Clorpactin gently lavaged in the bladder for 3 to 5 minutes without anesthesia; 14 patients reported subjective improvement (Wishard et al, 1957). Murnaghan noted improvement in 14 of 17 patients, although 10 required further treatment during the average 2-year follow-up (Murnaghan et al, 1970). Most commonly, the treatments are given as described by Messing and Stamey, using 0.4% solution administered at 10 cm water pressure under anesthesia (Messing and Stamey, 1978). Multiple instillations can be given, with a 1-month pause after the first two instillations to await a therapeutic response. Their success rate was 72% with an average 6-month duration of response. LaRock noted a 50% to 55% meaningful improvement rate occurring within 4 to 6 weeks of treatment (LaRock and Sant, 1995). A case of ureteral fibrosis complicating the treatment prompted the recommendation that vesicoureteral reflux be considered a contraindication to the procedure (Messing and Freiha, 1979). Our method of Clorpactin delivery is as follows:

1. Reflux is excluded with a cystogram.
2. Under anesthesia the bladder is distended for 2 minutes at 60 to 80 cm water pressure and emptied.
3. The perineum is shielded with a moistened towel.
4. A solution of 0.4% freshly prepared Clorpactin (4 g in 1000 mL of sterile water) is instilled by gravity drainage (the Foley catheter is held 10 cm above the level of the bladder) in 150- to 200-mL aliquots for a dwell time of 2 to 3 minutes and drained by gravity. This continues until the entire 1000 mL of solution has been used.
5. The bladder and introitus are then irrigated with normal saline and the catheter is removed.

Clorpactin is rarely used at the present time, and there is no current literature on this therapy. It is not a part of any guideline algorithm and has fallen out of favor.

1987) revealed symptomatic success rates higher than 80%, although relapse was not uncommon. Fowler noted only minimal improvements in functional bladder capacity and attributed the beneficial effects of DMSO to a direct effect on the sensory nerves of the bladder. Perez-Marrero compared DMSO with saline and showed a 93% objective improvement and 53% subjective improvement compared with 35% and 18%, respectively, for saline (Perez-Marrero et al, 1988). Patients with bladder instability do not respond (Emerson and Feltis, 1986). Stav and Hung reported 60% success rates and recommended it be considered a first-line therapy (Stav et al, 2012; Hung et al, 2012).

With its ease of administration (Biggers, 1986), low morbidity, and reasonable symptomatic results, DMSO certainly merits its place as a useful treatment for BPS/IC. In vivo studies on rat bladder strips exposed to various concentrations of DMSO for 7 minutes showed absence of electrical field stimulation contraction at a 40% concentration and diminished compliance at 30% concentration (Melchior et al, 2003). Concentrations of 25% or less had negligible effects in this model. How it relates to use of DMSO in humans is unknown. A rare case of eosinophilic cystitis has been reported after DMSO instillation (Abramov et al, 2004).

DMSO is often administered as part of an “intravesical cocktail” (50 mL Rimso-50 + 10 mg Kenalog + 44 mEq sodium bicarbonate + 20,000 to 40,000 units intravesical heparin) weekly for 6 weeks. If there is a good clinical response, maintenance therapy consisting of administration of the cocktail monthly for 6 months has been employed. There are no controlled studies as to the efficacy of this combined therapy, nor are there long-term safety studies reported. There is an inherent problem in doing placebo-controlled trials with DMSO because the strong garlic odor resulting from instillation quickly unblinds any trial.

Glycosaminoglycans

Exogenous GAGs have been shown to be effective in providing an epithelial permeability barrier in bladders in which the epithelium has been injured with protamine (Nickel et al, 1998). Heparin, which can mimic the activity of the bladder's own mucopolysaccharide lining (Hanno et al, 1978b), has anti-inflammatory effects as well as actions that inhibit fibroblast proliferation, angiogenesis, and smooth muscle cell proliferation. Because of its numerous effects, the possibility that heparin could be used for therapeutic reasons other than the control of coagulation has been the subject of much inquiry and speculation (Lane and Adams, 1993). Weaver first reported on the use of intravesical heparin for IC treatment (Weaver et al, 1963). Given intravesically, there is virtually no systemic absorption, even in an inflamed bladder (Caulfield et al, 1995). Although uncontrolled studies suggested some beneficial effect for subcutaneous administration (Lose et al, 1983, 1985), the obvious risks of anticoagulation and osteoporosis have prevented this form of administration from undergoing further trials and general usage. Ten thousand units can be administered intravesically in sterile water either alone or with DMSO at varying intervals with good results reported (Perez-Marrero et al, 1993; Parsons et al, 1994a). Kuo reported 50% or greater improvement in the International Prostate Symptom Score in 29 of 40 women with IC treated with 25,000 units intravesically twice weekly for 3 months (Kuo, 2001).

Parsons has used daily intravesical doses of 40,000 units of heparin in 20 mL of sterile water administered by the patient daily and held for 30 to 60 minutes. “Reasonable improvement of symptoms” can be expected between 6 months and 2 years after initiation of therapy (Parsons, 2000). Adding alkalized lidocaine to the heparin instillation provides better pain relief (Parsons, 2005). The addition of 8 mL of 2% lidocaine and 4 mL of 8.4% sodium bicarbonate may improve results (Welk and Teichman, 2008). In fact, a combination of 200 mg of lidocaine with 8.4% sodium bicarbonate (10 mL total solution) without heparin showed a 30% response rate 3 days after completion of daily intravesical administration for 5 days and was statistically superior to a placebo cocktail (Nickel et al, 2009b). A Japanese study reported high success rates with

weekly intravesical instillation of 20,000 units of heparin with 5 mL of 4% lidocaine and 25 mL of 7% sodium bicarbonate for 12 weeks (Nomiya et al, 2013). Intravesical administration of a solution of lidocaine and heparin has been proposed as a treatment for symptom flare (Parsons et al, 2012).

Another GAG analogue, PPS, administered intravesically (300 mg twice weekly in 50 mL of normal saline) showed some modest benefit in a small trial (Bade et al, 1997a). A 41-patient trial comparing oral PPS with oral and intravesical administration showed that the 24% reduction in O’Leary-Sant scores with oral therapy alone rose to a 46% reduction in the group that also received intravesical PPS (Davis et al, 2008).

The nonsulfated GAG hyaluronic acid has also been used intravesically. Trials using 40 mg dissolved in 40 mL of normal saline weekly for 4 to 6 weeks and then monthly treatments thereafter have had response rates varying from 71% (Morales et al, 1996) to 30% (Porru et al, 1997). In the summer of 2003 Bioniche Life Sciences and in the spring of 2004 Seikagaku Corporation reported double-blind, placebo-controlled, multicenter clinical studies of their hyaluronic acid preparations (40 mg or 200 mg per milliliter, respectively), and neither showed significant efficacy of sodium hyaluronate compared with placebo. These negative studies have not been published in peer-reviewed literature. Neither preparation has been approved for use for BPS/IC in the United States. An Austrian open-label study showed that 13 of 27 patients with BPS and a positive potassium test result responded to intravesical hyaluronic acid 40 mg weekly for 10 weeks, though initial nonresponders at 5 weeks also were treated with intravesical PPS 200 mg three times weekly for the remaining 5 weeks (Daha et al, 2008). The best results for hyaluronic acid come from Riedl, who studied 126 patients with a positive modified potassium test result who could hold the solution for 2 hours, using 40 mg weekly for a minimum 10 weeks; 84% had significant improvement (Riedl et al, 2008). Treatment-resistant cases have been managed with a combination of sequential bladder distention under anesthesia accompanied by a hyaluronic acid instillation every 1 to 3 months depending on response with a 74% success rate in 23 patients (Ahmad et al, 2008). Although hyaluronic acid has been seemingly efficacious in uncontrolled trials (Van Agt et al, 2011; Engelhardt et al, 2011; Figueiredo et al, 2011; Lv et al, 2012; Lai et al, 2013), the efficacy of hyaluronic acid for BPS/IC remains unproven in controlled and blinded trials (Iavazzo et al, 2007). It remains unapproved for BPS in the United States.

Chondroitin sulfate plays an important role for bladder barrier function (Janssen et al, 2013). Hurst has shown by immunohistochemistry a deficit of chondroitin sulfate from the luminal bladder surface in IC patients (Hurst, 2003). Intravesical chondroitin sulfate inhibited recruitment of inflammatory cells in an experimental “leaky bladder” model of cystitis (Engles et al, 2012). Small uncontrolled studies using intravesical chondroitin sulfate have shown success rates of 33% to 75% (Steinhoff et al, 2002; Sorensen, 2003; Tornero et al, 2013). A multicenter, open-label study using a 2% solution of sodium chondroitin sulfate weekly for 6 weeks and then monthly for 4 months had a 60% response rate with no safety issues (Nickel et al, 2009a). A larger follow-up study failed to demonstrate significant efficacy (Nickel et al, 2012; Thakkinstian and Nickel, 2013). A large open-label experience using the device for all forms of “chronic cystitis” concluded that it was effective in improving urgency, voided volumes, and nocturia, and well tolerated when administered weekly for a maximum of eight instillations (Nordling and van Ophoven, 2008).

The GAGs have been combined for instillation with good results reported in uncontrolled studies (Cervigni et al, 2008; Cervigni et al, 2012; Porru et al, 2012; Giberti et al, 2013).

A large analysis of GAG layer replenishment therapy with intravesical GAGs concluded that despite the fact that GAG intravesical therapy has been in use for over two decades, most of the studies have been uncontrolled, have been poorly done, and have had a small number of patients. Large-scale randomized controlled trials are urgently needed to underline the benefit of this type of therapy. Distinct patient groups (well phenotyped) need to be confirmed by

definite diagnostic findings (Madersbacher et al, 2013). Another review sadly concludes that “randomized controlled trials have suggested the GAG analogues are at best as good as placebo” (Chintea and Belal, 2013).

Other Intravesical Therapies

The use of doxorubicin, BCG, capsaicin, and resiniferatoxin (RTX) is described on the Expert Consult website.

KEY POINTS: INTRAVESICAL THERAPIES

- The potential for high efficacy combined with safety and a low side effect profile that is gained by applying a treatment directly to the bladder lining has made research into new methods of intravesical therapy a high priority of researchers and pharmaceutical companies.
- Patients in whom pain and other symptoms are not related directly to bladder pathology would not be expected to respond well to this type of organ-directed therapy.

Intradetrusor Therapies

The therapeutic value of **botulinum toxin type A (BTX-A)** stems partially from its ability to temporarily inhibit the release of acetylcholine and other neurotransmitters and to cause flaccid paralysis in a dose-related manner in skeletal muscle. It can correct focal dystonia when injected into a muscle. Intradetrusor BTX-A has now been approved for use in the United States in the management of refractory neurogenic and idiopathic DO. BTX-A also has analgesic properties (Rajkumar and Conn, 2004). Initially this effect was thought to be a result of relief of muscle spasm. However, botulinum has been shown to reduce peripheral sensitization by inhibiting the release of several neuronal signaling markers, including glutamate and substance P, and reducing *c-Fos* gene expression. It may affect the sensory feedback loop to the central nervous system by decreased input from the muscle tissue, possibly by inhibiting acetylcholine release from gamma motor neurons innervating intrafusal fibers of the muscle spindle (Rosales et al, 1996). It inhibits the release of sensory neurotransmitters from isolated bladder preparations in rat bladder models of both acute injury and chronic inflammation (Lucioni et al, 2008). Chronic inflammation and apoptosis is significantly reduced after repeated BTX-A injections in patients with BPS (Shie et al, 2013). BTX-A has been used effectively for years in different conditions with muscular hypercontractions. Intravesical BTX administration blocks the acetic acid-induced calcitonin gene-related peptide (CGRP) release from afferent nerve terminals in the bladder mucosal layer in rats (Chuang et al, 2004). In an animal model of bladder permeability barrier disruption, intravesical BTX-A minimized bladder irritability and restored afferent neural responses to baseline levels (Vemulakonda et al, 2005). These results support clinical trials of BTX-A for the treatment of BPS/IC and other types of visceral pain (Chancellor and Yoshimura, 2004).

A multi-institutional case series using Botox or Dysport intravesical injections in 13 patients with refractory BPS/IC reported improvement in 9 patients. Improvements in symptoms lasted a mean of 3.72 months (range 1 to 8 months). No systemic complications were observed, although 2 patients had a diminished flow with some need to strain to void (Smith and Chancellor, 2004). Rackley and colleagues at the Cleveland Clinic reported no change in objective or subjective outcome measures in a series of 10 BPS/IC patients in whom the trigone was spared in the injection technique (Rackley et al, 2005). A 1-year follow-up in 15 patients treated with 200 units of BTX-A in 20 mL of normal saline showed that the success rate fell from 86.6% at 3 months to 26.6% at 5 months and was 0 at 12 months (Giannantoni et al, 2008). Bladder biopsy 2 weeks after BTX-A intradetrusor injection showed that

nerve growth factor production levels fell to those of controls in patients who responded (Liu et al, 2009). It is hypothesized that treatment-refractory patients may have developed antibodies after initial BTX injection (Schulte-Baukloh et al, 2008).

The Portuguese group from Oporto has championed limiting injections to 100 units divided into 10 injection sites, all in the trigone. More than 50% of patients experienced efficacy with a duration of 9 months, and no voiding dysfunction was noted (Pinto et al, 2010). There appears to be little tachyphylaxis associated with the treatment, and repeated injections at regular intervals or when symptoms recur remain effective (Kuo, 2013; Pinto et al, 2013). Onabotulinum toxin A appears to be a reasonable treatment for BPS that is refractory to standard conservative, oral, and intravesical treatment (Mangera et al, 2011; Yokoyama et al, 2012). When injected into the trigone in 10-unit aliquots (100 units total), the risk of impaired bladder emptying seems to be minimized.

Submucosal injection of 10 mL of 40 mg/mL **triamcinolone acetonide** injected in 0.5-mL aliquots was used for the treatment of Hunner lesions in 30 patients (Cox et al, 2009). Seventy percent of patients were very much improved, and duration of improvement was estimated to be 7 to 12 months.

Neuromodulation

Because PBS/IC is a chronic pain syndrome, it is reasonable to consider therapeutic options that directly interface with the nervous system. This approach is further supported by the association of pelvic floor dysfunction with pelvic pain syndromes (Zermann et al, 1999).

Pain diversion by **transcutaneous electrical nerve stimulation (TENS)** is routine in a variety of painful conditions (Fall, 1987). Fall and colleagues were the first to use electrical stimulation in IC, reporting on 14 women treated successfully with long-term intravaginal nerve stimulation or TENS (Fall et al, 1980). Subsequently McGuire noted improvement in 5 of 6 patients treated with electrical stimulation (McGuire et al, 1983).

The primary intention in applying peripheral electrical nerve stimulation in IC is to relieve pain by stimulating myelinated afferents to activate segmental inhibitory circuits. As a secondary effect, urinary frequency may also be reduced. In the most complete review of the subject (Fall and Lindstrom, 1994), 33 patients with ulcerative IC and 27 patients with nonulcerative IC were treated by means of suprapubic TENS. Electrodes were positioned 10 to 15 cm apart immediately above the pubic symphysis. High- or low-frequency (2 to 50 Hz) TENS was employed. If there was no effect with high-frequency TENS after 1 month, low-frequency TENS was used. Application of 30 to 120 minutes of TENS was prescribed daily. Pain improved more than frequency. Good results or remission was described in 26% of nonulcerative IC patients and a surprising 54% of patients with ulcerative disease. Fall and Lindstrom (1994) caution that the experience is based on open studies, relatively few patients, and the knowledge of a significant placebo effect with peripheral pain stimulation.

Acupuncture has been used to treat frequency, urgency, and dysuria (Chang, 1988). Twenty-two of 26 patients treated at the SP 6 point had clinically symptomatic improvement. A study looking at both acupuncture and TENS in IC showed limited effects of both modalities (Geirsson et al, 1993). Lumbar epidural blockade was the subject of a positive case report (Pelaiez et al, 2004), but in an earlier series resulted in only short-term (mean 15 days) pain relief in IC (Irwin et al, 1993). Posterior tibial nerve stimulation was successful in 60% of 37 patients with symptoms of bladder overactivity in an uncontrolled Dutch study (van Balken et al, 2001). An Australian double-blind placebo-controlled study of transdermal posterior tibial nerve laser therapy showed no benefit in 56 patients when comparing active with placebo arms, but the placebo effect was remarkably strong, indicating the importance of such trials in evaluation of invasive therapies (O'Reilly et al, 2004). A Chinese study of posterior tibial nerve stimulation twice weekly for 5 weeks in BPS/IC patients failed to show improvement in pain scores, and

Doxorubicin (Khanna and Loose, 1990) and the mast cell stabilizer **cromolyn sodium** (Edwards et al, 1986; Kennelly and Konnak, 1995) have been tried in pilot trials with the promising results we have come to expect in such studies. Follow-up studies are lacking, and these drugs have not become a part of the intravesical pharmacopoeia.

The use of intravesical **bacillus Calmette-Guérin (BCG)** for IC was first reported by Zeidman and colleagues (1994). A subsequent randomized, prospective, double-blind, placebo-controlled trial of 30 patients treated weekly for 6 weeks and followed for a mean of 8 months noted a 60% response rate compared with a 27% placebo response (Peters et al, 1997). Surprisingly, BCG was tolerated as well as placebo. Even more surprisingly, 8 of 9 BCG responders continued to have an excellent response in all parameters measured at 27 months of follow-up (Peters et al, 1998). It is unclear how BCG achieved this result, but immunologic and/or anti-inflammatory mechanisms have been postulated (Peters et al, 1999). A double-blind crossover Swedish study comparing DMSO with BCG failed to substantiate BCG efficacy (Peeker et al, 2000c).

A large multicenter randomized controlled trial by NIDDK comparing BCG with placebo found a 12% response rate for placebo compared with a 21% response for BCG. Placebo responders in the trial had the same durability of response (up to 68 weeks) as the BCG responders (Propert et al, 2008). In a follow-up open-label phase of the trial, the response rate was 18% in both the group originally randomized to BCG and the group initially randomized to placebo, indicating that a second course of therapy does not improve response rate (Propert et al, 2007). The small response rate in the RCT failed to reach statistical significance at the $P = .05$ level, and this large study of 265 patients suggests that **BCG has no place in the treatment of moderate to severe BPS/IC** (Mayer et al, 2005). The BCG safety profile was considered acceptable in the NIDDK trial, but adverse events were not uncommon, and rare hypersensitivity reactions to intravesical BCG can occur (Parker et al, 2004). Although small uncontrolled trials showing efficacy of BCG have been reported (Aghamir et al, 2007; El-Bahnasy et al, 2009), the NIDDK trial dampened enthusiasm for this treatment modality.

Efforts to bring new therapies directly to the bladder continue to be the focus of investigators. Oxybutinin has shown efficacy in preliminary studies when administered intravesically at doses of 10 mg dissolved in saline (Bade et al, 2000; Barbalias et al, 2000). Electromotive drug administration, the active transport of ionized drugs by the application of an electric current, using lidocaine and dexamethasone has shown a 25% success rate up to 6 months after instillation (Rosamilia et al, 1997). A similar trial using repeated instillations noted success rates of 60% with a mean duration of 6.6 months (Riedl et al, 1997). **Capsaicin**, the main pungent ingredient in hot peppers of the genus *Capsicum*, is a specific neurotoxin that desensitizes C-fiber afferent neurons. **Resiniferatoxin (RTX)**, an ultra-potent analogue of capsaicin, appears to have similar effects with less of the acute pain and irritation associated with capsaicin application. Both compounds have been tested intravesically for the relief of bladder instability and hyperreflexia (Chancellor and de Groat, 1999). Clinical trials of the use of these compounds in bladder pain, urgency, and frequency could show this to be a new and viable treatment modality in the future, but **current data on efficacy in BPS are lacking** (Lazzeri et al, 1996; Lazzeri et al, 2000; Cruz et al, 1997). A phase 2 safety and proof-of-concept multicenter, placebo-controlled trial conducted by ICOS Corporation of Bothell, Washington found no significant efficacy of a single intravesical administration of RTX compared with placebo, although no safety issues were identified (Payne et al, 2005). Use of RTX and hydrodistention was effective in relieving the pain of BPS when compared with hydrodistention alone, but was not effective in improving lower urinary tract symptoms (Ham et al, 2012). Studies using other concentrations and multiple administrations may be worthwhile (Peng and Kuo, 2007).

Liposomes, vesicals composed of concentric phospholipid bilayers separated by aqueous compartments, adsorb onto cell surfaces and fuse with cells. They can be used for drug delivery and gene therapy. They are currently in testing as an intravesical therapy for BPS (Fraser et al, 2003; Lee et al, 2011b).

none of the 18 patients thought the treatment had a significant effect (Zhao et al, 2008).

Direct sacral nerve stimulation has been explored in the treatment of BPS and urgency and frequency and is referred to as **neuromodulation**, a technique whose urologic potential was developed through the basic and clinical research of Tanagho and Schmidt (Schmidt, 1993; Fandel and Tanagho, 2005). They and others have observed that patients who do best with this treatment modality are those who have identifiable pain and dysfunction in the pelvic muscles (Everaert et al, 2001; Siegel et al, 2001; Aboseif et al, 2002). Patients reporting pelvic pain in the absence of demonstrable pelvic floor dysfunction and levator tenderness did poorly (Schmidt, 2001). As initially practiced, trial stimulation was performed with a percutaneous temporary electrode for a 3- to 4-day temporary stimulation period to access efficacy. The S3 nerve was most frequently used. A wire electrode was inserted into the foramen and connected to an external pulse generator (Medtronic, Minneapolis, MN). If the trial was successful, the patient was considered for implantation of a permanent neural prosthesis. More recently, a staged procedure has supplanted the traditional percutaneous approach, as the response to stimulation can be better assessed with more accurate lead placement and stability than through the more hit-or-miss percutaneous lead placement (Peters et al, 2003). Peters's test-to-implant rate increased from 52% to 94%. Other reports have noted a test-to-implant rate with the percutaneous technique of 76% in 33 PBS/IC patients (Whitmore et al, 2003) to 40% in 211 patients with refractory urge incontinence, urgency-frequency syndrome, and urinary retention (Scheepens et al, 2002b).

Neuromodulation has been shown to be effective in treating refractory urinary urge incontinence (Schmidt et al, 1999; Spinelli et al, 2001). Studies on therapeutic potential in BPS/IC followed (van Kerrebroeck, 1999). The University of Maryland group described a decrease in antiproliferative activity and normalization of HB-EGF levels in patients with successful test stimulation (Chai et al, 2000a). Peters and coworkers reported success in two thirds of BPS/IC patients with sacral nerve stimulation (Peters et al, 2003). GRA score as determined by the patients correlated with objective findings (Peters et al, 2008). Another study (Comiter, 2003) noted that 17 of 25 patients were successful with test stimulation and went on to permanent implantation of the InterStim device (Medtronic, St. Paul, MN). Devices in 13 of 15 who underwent staged implantation were permanently implanted versus in 4 of 10 undergoing percutaneous test stimulation. With a mean follow-up of 14 months, 16 of 17 patients were judged to have a successful outcome, yielding an intent-to-treat success rate of 64%. Although sacral neuromodulation can decrease narcotic requirements significantly in refractory BPS/IC, the majority of patients taking chronic narcotics for pain will likely continue to use them for pain relief even after implantation (Peters and Konstant, 2004). One center reported a long-term improvement rate of 45% for the urgency and frequency indication (Elhilali et al, 2005). Treatment results do not appear to be age dependent (Peters et al, 2013b). Sexual functioning in women may improve as well (Yih et al, 2013). **Several studies now attest to the benefits of sacral neuromodulation for BPS (Ghazwani et al, 2011; Marinkovic et al, 2011; Vaarala et al, 2011; Tirlapur et al, 2013b).**

Unilateral stimulation should be performed before bilateral sacral stimulation is considered (Oerlemans and van Kerrebroeck, 2008). A bilateral test stimulation could be indicated when a unilateral test fails (Steinberg et al, 2007). The only prospective randomized crossover trial to compare the unilateral with bilateral sacral nerve stimulation found no significant differences comparing the results (Scheepens et al, 2002a). The presence of pain is a predictor of adverse events (White et al, 2009), and although sacral neuromodulation is effective in 56% of patients with urgency and frequency, when pain is the major complaint, caution is indicated. Nevertheless, **reviews of multiple, largely uncontrolled anecdotal studies show success rates of 60% to 80% for chronic pelvic pain (Marcelissen et al, 2011; Srivastava, 2012). Surgical revision rates are 7% to 0% (van Kerrebroeck et al, 2007; Gajewski and Al-Zahrani, 2011).** When used for BPS symptoms, frequent reprogramming is

often required (Maxwell et al, 2008). The presence of urgency may be a positive predictor of long-term success (Gajewski and Al-Zahrani, 2011).

KEY POINTS: NEUROMODULATION

- The association of pelvic floor dysfunction with pelvic pain syndromes makes neuromodulation a rational therapeutic alternative.
- Patients with pelvic pain in the absence of demonstrable pelvic floor dysfunction and levator tenderness may not respond as well as those with urgency and frequency associated with pelvic floor dysfunction. Controlled trials of sacral nerve stimulation for BPS are needed.

Surgical Therapy

Hydrodistention

Hydrodistention of the bladder under anesthesia, while technically a surgical treatment, is often the first therapeutic modality employed, often as a part of the diagnostic evaluation. **Because there have been no standard methods of distention (Turner and Stewart, 2005), results vary markedly.** Frontz first suggested hydraulic overdistention of the bladder for IC in 1922 (Frontz, 1922), and Bumpus reported the first series 8 years later (Bumpus, 1930). Simple bladder filling at cystoscopy will give relief to some patients (Hald et al, 1986); other researchers have reported use of an office-based procedure with intravesical lidocaine anesthesia and electromotive drug administration (Rose et al, 2005); and Dunn reported on 25 patients undergoing distention under anesthesia to the level of the systolic blood pressure for up to 3 hours (Dunn et al, 1977). Sixteen of the patients were symptom free with a mean follow-up of 14 months; 2 patients experienced bladder rupture. **The bladder in IC patients can be very thin, and the possibility of perforation or rupture must always be kept in mind and discussed with the patient (Badenoch, 1971; Hamer et al, 1992). Prolonged distention probably has little or no benefit over a short-term distention measured in minutes (Taub and Stein, 1994; McCahy and Styles, 1995).** Using epidural anesthesia and a balloon distention technique to the mean arterial pressure for 3 hours continuously, Glemain and colleagues reported good but transient efficacy in patients with a bladder capacity greater than 150 mL on predistention cystometry (Glemain et al, 2002). In their prospective series of 30 patients, 18 had maintained a therapeutic response at 6 months and 13 at 1 year of follow-up. Moderate hematuria was almost universal, worsening of symptoms occurred in 5% of patients, and low back and hypogastric pain were common sequelae. One bladder rupture, one episode of sepsis, and one episode of prolonged retention occurred.

Our method is to perform an initial cystoscopic examination (the findings of which are usually unremarkable), obtain urine for cytology, and distend the bladder for 1 to 2 minutes at a pressure of 80 cm H₂O. The bladder is emptied and then refilled to allow observation for glomerulations or ulceration. A therapeutic hydraulic distention follows for another 8 minutes. Biopsy, if indicated, is performed after the second distention. Therapeutic responses in patients with a bladder capacity under anesthesia of less than 600 mL showed 26% with an excellent and 29% with a fair result compared with 12% excellent and 43% fair in patients with larger bladder capacities (Hanno and Wein, 1991). Most favorable responses were extremely brief, however, with the exceptional patient noting improvement for 6 months, thus being a candidate for repeat therapeutic distention.

Acute hydrodistention does not seem to result in any long-term bladder dysfunction (Kang et al, 1992; Lasanen et al, 1992). Any efficacy is probably related to damage to mucosal afferent nerve endings (Dunn et al, 1977). It has no benefits in patients with DO

(Taub and Stein, 1994; McCahy and Styles, 1995). Over half of men with prostate pain and without bacteriuria may have glomerulations. Symptoms in this group have been reported to improve with hydrodistention (Berger et al, 1998). Although many patients with IC have sensory urgency at awake capacities of less than 100 mL, hydrodistention under anesthesia seems to allow for “staging” of the disease, giving the clinician some idea of the capacity he or she has to work with conservative therapies. A capacity under anesthesia of under 200 mL would not bode well for the likelihood of success of medical therapy. Fortunately, these cases are relatively rare.

Surgical Considerations

Major extirpative and/or reconstructive surgical therapy for BPS is an option after all trials of conservative treatment have failed—a point that cannot be overemphasized. BPS/IC, although a cause of significant morbidity, is a nonmalignant process with a temporary spontaneous remission rate of up to 50% (Held et al, 1990) that does not directly result in mortality. Deaths are either self-inflicted or the result of complications of therapy. Nowhere does the caveat *primum non nocere* bear more relevance; the treatment must be no worse than the disease process (Siegel et al, 1990). Surgery should be reserved for the motivated and well-informed patient who falls into the category of having extremely severe, unresponsive disease, a group that comprises less than 10% of patients (Irwin and Galloway, 1994; Parsons, 2000).

Historical Procedures

Many surgical approaches have been employed for IC, and it is worth mentioning a few for historical perspective alone. Sympathectomy and intraspinal alcohol injections have been used to treat pelvic pain (Greenhill, 1947). Differential sacral neurotomy was reported in 3 patients with good results (Meirowsky, 1969), but like most deinnervation procedures never gained popularity because of subsequent poor results. Transvesical infiltration of the pelvic plexuses with phenol failed in 5 of 5 patients with IC (Blackford et al, 1984). With a significant complication rate of 17% (McInerney et al, 1991), it is rarely if ever currently used for sensory urgency disorders or detrusor hyperreflexia. There are several reports on cystolysis going back to Richer in 1929 (Bourque, 1951). Worth and Turner-Warwick reported some short-term benefit, but unpredictable long-term results (Worth and Turner-Warwick, 1973; Worth, 1980). Freiha and Stamey used cystolysis in 6 IC patients with good results in 4 (Freiha and Stamey, 1979). Albers reported long-term follow-up in 11 IC patients and only 1 success (Albers and Geyer, 1988). Denervation procedures have a notoriously high late-failure rate, and the procedure is not justified for BPS/IC (Walsh, 1985; Stone, 1991). In fact, Rogers has concluded that there exist no convincing clinical studies to recommend surgical procedures to interrupt visceral nerve pathways in women with any type of chronic pelvic pain (Rogers, 2003).

Surgery for Hunner Lesion

Transurethral resection of a Hunner lesion as initially reported by Kerr can provide symptomatic relief (Kerr, 1971). Fall resected ulcerated lesions in 30 patients, resulting in initial disappearance of pain in all and a decrease in urinary frequency in 21 (Fall, 1985). Similar results have been attained with the neodymium-yttrium-aluminum-garnet (YAG) laser (Shanberg et al, 1985, 1989; Rofeim et al, 2001). The majority of patients require repeat fulguration as recurrence of the lesions and symptoms is to be expected over ensuing months to years (Hillelsohn et al, 2012). Extreme caution is critical with use of a laser in a BPS/IC bladder, because forward scatter through these thin bladders with resulting bowel injury is an ever-present danger. There would seem to be no justification in the literature for using the laser to treat areas of glomerulation or in the nonulcerative form of the disease (Shanberg et al, 1997).

Major Surgical Procedures

Supratrigonal cystectomy and the formation of an enterovesical anastomosis with bowel segments (substitution cystoplasty) has been a popular surgical procedure for intractable IC. The diseased bladder is resected in its entirety, sparing only a 1-cm cuff around the trigone to which the bowel segment is anastomosed (Worth et al, 1972; Irwin and Galloway, 1994). Although it is not always clear in the literature how much bladder has been resected, the results reported using these procedures for IC have been mixed at best. Badenoch operated on 9 patients, with 4 becoming much worse and 3 ultimately undergoing urinary diversion (Badenoch, 1971). Flood and colleagues reviewed 122 augmentation procedures, 21 of which were done for IC. Patients with IC had the poorest results of any group, with only 10 having an “excellent” outcome (Flood et al, 1995). Wallack reported 2 successes (Wallack et al, 1975); Seddon had success in 7 of 9 patients (Seddon et al, 1977); and Freiha ended up performing formal urinary diversion in 2 of 6 patients treated with augmentation cecocystoplasty (Freiha et al, 1980). Weiss had success in 3 of 7 patient treated with sigmoidocystoplasty (Weiss et al, 1984), and Lunghi had no excellent results in 2 patients with IC (Lungi et al, 1984). Webster reviewed his data in 19 patients and concluded that only patients with bladder capacities under anesthesia less than 350 mL should undergo substitution cystoplasty (Webster and Maggio, 1989). Hughes lowered the threshold to less than 250 mL (Hughes et al, 1995).

More recent series on subtotal cystectomy plus augmentation have been somewhat more positive (Costello et al, 2000; Chesa et al, 2001). Peeker had good results in all 10 patients with ulcerative IC but poor results in the 3 patients operated on with nonulcerative disease (Peeker et al, 1998). He no longer performs the procedure in the latter group. Linn had success in 20 of 23 patients (only 2 with ulcerative IC) treated with subtotal cystectomy and orthotopic bladder substitution with an ileocecal pouch (Linn et al, 1998). He recommends a supratrigonal cystectomy. A Spanish series reported success in 13 of 17 procedures with a mean follow-up of 94 months (Rodriguez Villamil et al, 1999). The University of Alabama group reported long-term success in 1 of 4 patients with orthotopic neobladders and 1 of 3 with augmentation cystoplasty (Lloyd, 1999). A German report on substitution cystoplasty sparing the trigone was quite enthusiastic, detailing a 78% pain-free rate in 18 patients treated with ileocecal augmentation (10) or ileal substitution (8) at a mean follow-up of 57 months (van Ophoven et al, 2002). Two patients failed to get any pain relief, and 4 required either long-term intermittent catheterization or suprapubic drainage to empty the neobladder.

Not all patients empty the bladder spontaneously after substitution cystoplasty. Although the need for clean intermittent catheterization would not obviate a successful outcome in the patient treated for bladder contraction from tuberculous cystitis, it can be a painful disaster in the IC patient. Nurse and colleagues have gone one step further, recommending trigone biopsy before substitution cystoplasty (Nurse et al, 1991). Diversion and/or total cystourethrectomy is recommended if the trigone is affected by IC. It is not clear how this is determined histologically, as IC has no pathognomonic findings by histology and in general is not a localized process. Nielsen and coworkers described eight women treated with substitution cystoplasty (Nielsen et al, 1990). Treatment in six patients failed, and the results of postoperative biopsies from the trigone showed no difference in the amount of fibrosis, degree of degenerative changes in the muscle, and mast cell density between the two cured patients and the others.

There has been a controversy over whether the IC process can occur in a transposed bowel patch (McGuire et al, 1973; Kisman et al, 1991; Singh and Thomas, 1996) or even in the ureter (Smith and Christmas, 1996). If so, not only would this be a relative contraindication to bladder augmentation, but it would also provide support for the view that a substance in the urine might be involved in pathogenesis. There is, however, evidence that inflammation and fibrosis are the usual reactions of bowel to exposure to urine;

therefore, pathologic findings alone would not be conclusive of spread of IC in such patients (MacDermott et al, 1990).

Augmentation cystoplasty has many potential complications, from the rare incidence of bladder neoplasm (Golomb et al, 1989) to the more common complication of upper tract obstruction (Cheng and Whitfield, 1990). In the best of hands, complications can involve almost 50% of patients, necessitating surgical intervention in 25% (Khoury et al, 1992; Bunyaratavej et al, 1993). Although problems are more common in patients operated on for disorders other than IC, the risk-benefit ratio of substitution cystoplasty seems to have discouraged its use in the last several years.

Urinary diversion with or without cystourethrectomy is the ultimate surgical answer to the dilemma of IC, akin to cutting the “Gordian knot.” If diversion alone is chosen, one must keep in mind potential problems that can befall the remaining bladder, including pyocystis, hemorrhage, severe pain, and unremitting feelings of incomplete emptying and spasm (Eigner and Freiha 1990; Adeyoku et al, 1996). Bladder carcinoma has also been reported after urinary diversion but is not specifically associated with BPS (Hanno and Tomaszewski, 1982). Consideration of cystourethrectomy is indicated only in patients who are miserable, in whom all other therapies have failed, and who have demonstrated chronicity such that remission is considered extremely unlikely. Fortunately, few patients fall into this category. Theoretically, conduit diversion seems to be reasonable if one is concerned about disease occurring in any continent storage type of reconstruction. The extended simple cystectomy performed for intractable IC may lend itself to anterior enterocele formation from weakening of the anterior vaginal wall, and prevention of this entity is warranted at the time of cystectomy (Anderson et al, 1998).

Bejany and Politano reported excellent results in 5 patients treated with total bladder replacement and recommended neobladder reconstruction (Bejany and Politano, 1995). Keselman and colleagues had 2 failures in 11 patients treated with continent diversion and attributed this to surgical complications (Keselman et al, 1995). A Finnish group noted failure in 2 of 4 patients treated with cystectomy and conduit diversion because of persistent pain (Lilius et al, 1973). Baskin and Tanagho also cautioned about persistence of pelvic pain after cystectomy and continent diversion, discussing 3 such patients (Baskin and Tanagho, 1992). A similar report followed (Irwin and Galloway, 1992). Webster and coworkers had 10 failures in 14 patients treated with urinary diversion and cystourethrectomy (Webster et al, 1992). Ten patients had persistent pelvic pain, and 4 of them also complained of pouch pain. Only 2 patients had symptom resolution. An English study of 27 patients who underwent cystectomy and bladder replacement with a Kock pouch noted successful treatment of pain in all patients, but follow-up was limited (Christmas et al, 1996a). Parsons suggests that pouch pain will occur in 40% to 50% of patients within 6 to 36 months of surgery (Parsons, 2000).

Attempts have been made to improve results by limiting the operation to those without detrusor mastocytosis (Trinka et al, 1993) and those without “neuropathic pelvic pain” (Lotenfoe et al, 1995). Based on the experience of the past decades, it is unclear if these efforts will prove any more successful. It would seem that risks of failure peculiar to IC include both the development of pain over time in any continent storage mechanism that is constructed, and the risk of phantom pain in the pelvis that persists despite the fact that the stimulus that initially activated the nociceptive neurons (diseased bladder) has been removed (Cross, 1994). Brookhoff has proposed trying a differential spinal anesthetic block before considering cystectomy (Brookhoff and Sant, 1997). If the patient continues to perceive bladder pain after a spinal anesthetic at the T10 level, it can be taken as an indicator that the pain signal is being generated at a higher level in the spinal cord and that surgery on the bladder will not result in pain relief. Some patients with intractable urinary frequency will opt for simple conduit urinary diversion alone, feeling that their quality of life will be improved independent of the pain piece of the puzzle. Despite all of the problems, many patients will do well after major surgery, and quality of life can measurably improve (Rupp et al, 2000). In the

event of neobladder pain after subtotal cystectomy and enterocystoplasty or continent diversion, it appears safe to retubularize a previously used bowel segment to form a urinary conduit for a straightforward urinary diversion without significant risk of conduit pain (Elzawahri et al, 2004).

The Gothenburg experience was recently reviewed, looking at results in 47 patients subjected to reconstructive or extirpative surgery (Rössberger et al, 2007). This included 23 substitution cystoplasties, 12 conduit diversions, and 10 Kock pouches. Twenty-eight of 34 patients with classic Hunner lesions had complete symptom resolution from the initial surgical procedure. Four of the remaining 6 required urinary diversion, cystectomy, or ulcer resection in a trigonal remnant, but ultimately did well. Only 3 of 13 patients with non-Hunner disease had successful symptom resolution after reconstructive surgery, 2 of whom required conduit diversion. Peeker's group concluded that only patients with Hunner lesions refractory to standard therapy could be expected to do well after major surgery.

A Thai experience using cystectomy and ileal neobladder in women in whom conservative therapy failed reported good results in all 35 patients treated (Kochakarn et al, 2007). Spontaneous voiding with minimal residual urine was found in 33 patients, and the remaining 2 patients had spontaneous voiding with residual urine requiring clean intermittent catheterization.

Forty years ago, Pool recognized that “surgical treatment has not been the boon many had hoped it would be” (Pool, 1967). “Diversion of the urine is not the entire answer to the situation. Removal of the lesion in the bladder has been of no benefit. Likewise, removal of almost the entire mobile portion of the bladder proved to be a failure.” Blaivas and colleagues (2005) described results of augmentation enterocystoplasty and continent diversion in 76 consecutive patients with benign disease with a mean 9-year follow-up. The procedures in all 7 patients with the diagnosis of IC were classified as failures, whereas 67 of the remaining 69 patients were cured or improved. When one of the deans of major urologic reconstruction writes, “I find it very difficult to justify such extensive surgery (continent diversion, cystourethrectomy) with such limited results and for these reasons have not been involved in surgery for IC over the past 3 years” (Webster, 1993), it is obvious that one should think carefully and proceed with surgery only after a complete discussion with a very motivated and well-informed patient. Recent reports seem to be more sanguine with regard to these procedures.

KEY POINTS: SURGICAL THERAPY

- Major surgery for BPS is a reasonable alternative for patients with severe symptoms in whom standard attempts at treatment have failed and when the disease course suggests that spontaneous remission of symptoms is unlikely.
- Patients with a small bladder capacity under anesthesia are less likely to respond to conservative attempts at therapy.
- Patients with a Hunner lesion may have the best results with major surgery.
- If one conceptualizes BPS as two disorders, one of pain and the other of frequency, it becomes easier for the patient and physician to rationalize the decision.
- Conduit urinary diversion can be relied on to resolve the frequency symptoms, and if the patient would consider this alone to make for a successful procedure, there is reason to seriously consider this option.
- Diversion, and even cystectomy with diversion, cannot guarantee a pain-free result, and it is critical for the patient to factor this into the decision about this often irrevocable step.

A simple ileal conduit without cystectomy or attempt at continent diversion can be an acceptable treatment choice with good clinical results and resulting quality-of-life improvement (Norus et al, 2014). Cystectomy may add complications and need for

reoperation (Peters et al, 2013a). Subtotal cystectomy with bladder augmentation may fail to give pain relief in more than one third of patients (Andersen et al, 2012).

Assessing Treatment Results

The diversity of BPS/IC therapies underscores the lack of understanding about the treatment of this syndrome (Rovner et al, 2000). It has been not only a difficult condition to diagnose, but also a difficult condition for which to assess therapeutic impact. There is a 50% incidence of temporary remission unrelated to therapy, with a mean duration of 8 months (Held et al, 1990). A recent meta-analysis of articles published from 1990 to 2010 on management of BPS/IC concluded that there is limited evidence proving efficacy of treatment and attributed the lack of definitive conclusions to the great heterogeneity in methodology, symptom assessment, duration of treatment, and follow-up in both randomized controlled trials and nonrandomized reports (Giannantonio et al, 2012). This should not be interpreted to conclude that all treatments for the affected individual are ineffective, but rather that demonstrating treatment effects in populations of patients has been problematic for the reasons noted. The lack of knowledge about how the syndrome should be best phenotyped stands out as an important missing piece.

A somewhat surprising finding from the ICDB was that although there was initial improvement in symptoms partially because of regression to the mean (Sech et al, 1998) and the intervention effect, there was no evidence of a long-term change in average symptom severity over the 4-year course of follow-up (Proper et al, 2000). In a chronic, devastating condition with primarily subjective symptomatology, no known cause, and no cure, patients are desperate and often seem to respond to any new therapy (Fig. 14-11). They are often victims of unorthodox health care providers with untested forms of therapy—some medical, some homeopathic, and some even surgical.

The Placebo Conundrum

Where possible, the results of randomized controlled studies should be used for decision making. Placebo-controlled, double-blind studies are optimal in this disorder for which there is no generally effective standard therapy.

Placebo effects influence patient outcomes after any treatment that the clinician and patients believe is effective, including surgery. Placebo effects plus disease natural history and regression to the mean can result in high rates of good outcomes, which may be misattributed to specific treatment effects (Gillespie et al, 1991; Gillespie, 1994; Turner et al, 1994; Proper et al, 2000). Unfortunately, too few BPS treatments have been subjected to a placebo-controlled trial. This is not to say that what seems effective is not, but rather that a high index of skepticism is healthy, even in treatments tested in controlled trials (Schulz et al, 1995).

Whereas in many diseases an argument can be made against using a true placebo control as opposed to an orthodox treatment of approved or accepted value (Rothman and Michels, 1994), a good case for true placebo comparison can readily be made for BPS. The vagaries of the natural history, the general lack of progression of symptom severity over time, and the fact that the condition is not life-threatening mean that there is little to lose and much to gain by subjecting new treatments to the rigorous scrutiny of placebo control. Many patients who volunteer for such trials have already run the gamut of accepted (although, in general, unproved) therapies. It has long been recognized in protocols that use subjective criteria for assessment that “improvement” may be expected in up to 35% of placebo-treated patients (Benson and Epstein, 1976). The spontaneous remission rate (although temporary) for BPS is 11% (Oravisto and Alfthan, 1976) to 50% (Held et al, 1990), and this in combination with the placebo improvement make efficacy difficult to prove.

Even in placebo-controlled trials, it is reasonable to surmise that some degree of unblinding may occur as a result of somatic or

Figure 14-11. Selected reported treatment outcomes in uncontrolled studies in the bladder pain syndrome and interstitial cystitis literature: Percentage of patients initially improved. Ag nitrate, silver nitrate; BCG, bacillus Calmette-Guérin; DMSO, dimethyl sulfoxide; PPS, sodium pentosan polysulfate; TENS, transcutaneous electrical nerve stimulation.

psychological side effects of the active arm, impairing the validity of the trial results and giving the active arm a slight edge over placebo (DuBeau et al, 2005; Rees et al, 2005). Failure to recognize unblinding can easily bias results of a study and has not been routinely measured in clinical trials (Desbiens, 2002). When

occurring late in a study after one would expect onset of a therapeutic effect, unblinding could be the result of side effect profile or drug efficacy. Early in the trial it reflects poor placebo or study design. The degree of blinding needs to be ascertained throughout the trial. This is of specific concern in BPS and any disorder in which primary outcomes may be subject to patient-specific psychological and physiologic factors.

The ethics and necessity of placebo-controlled trials have been questioned, especially in situations in which an effective treatment exists and also in which delay in treatment has been shown to result in disease progression (Streiner, 1999; Anderson, 2006; Polman et al, 2008). However, there are methodologic concerns with equivalence and noninferiority active agent comparison trials (Streiner, 2007). These include an inability to determine if the treatments are equally good or equally bad and the possibility that successive noninferiority trials can lead to a gradual decrease in treatment efficacy. Although the use of placebo-controlled trials raises ethical concerns when proven effective treatment exists for the condition under investigation, they are ethically justified, provided that stringent criteria for protecting research subjects are satisfied (Miller et al, 2004).

The value of placebo-controlled trials is aptly illustrated by the recent decisions by pharmaceutical manufacturers not to pursue FDA approval in the United States for seemingly promising intravesical therapies for BPS/IC (Morales et al, 1996; Chancellor and de Groat, 1999) after placebo-controlled trials failed to establish efficacy. These include low-concentration hyaluronic acid (Bioniche, Canada), high-concentration hyaluronic acid (Seikagaku, Tokyo), and RTX (ICOS, Bothell, WA). Nalmefene, an initially promising oral therapy in the 1990s (Stone, 1994), also failed phase 3 trials (IVAX, Miami, FL). Placebo trials are impractical in surgery, and it can be difficult to evaluate surgical reports. The many older medications currently used off-label might not meet success if tested in the stringent manner in which new molecular entities are tested. The expense of testing therapies currently used off-label often requires dependence on the largesse of government agencies such as the National Institutes of Health (Probert et al, 2002; Sant et al, 2003; Mayer et al, 2005).

Finally, in considering objective changes, the concept of statistical versus clinical significance is paramount. Investigators should, but rarely do, point out differences between statistical improvement and what they consider to be clinically significant improvement (Wein and Broderick, 1994). As Gertrude Stein reportedly stated, "A difference, to be a difference, must make a difference." An increase in bladder capacity of 30 mL may be statistically significant but clinically irrelevant. Number-needed-to-treat and number-needed-to-harm data (McQuay, 2003) may be particularly important in BPS/IC and have not typically been included in efficacy analysis.

Clinical Symptom Scales

BPS/IC symptom questionnaires include the University of Wisconsin Interstitial Cystitis Inventory, the O'Leary-Sant IC symptom index and IC problem index, and the Pelvic Pain and Urgency/Frequency (PUF) scale.

The University of Wisconsin IC scale includes seven PBS/IC symptom items (Table 14-5). It has not been validated for identification or diagnosis of BPS/IC. It captures severity of symptom expression (Keller et al, 1994; Goin et al, 1998). BPS/IC patients do not appear to indiscriminately report higher scores than controls for different somatic and general complaints (Porru et al, 2005). Unlike the other two instruments, it addresses some quality-of-life issues, and this is an advantage when such issues are subject of investigation. Its most attractive aspects are its clinically apparent face validity and its ease of implementation.

The O'Leary-Sant indices (Table 14-6) are a validated questionnaire that was originally developed by focus groups, subjected to test-retest reliability analysis, and validated by administration to IC patients and asymptomatic controls (O'Leary et al, 1997; Lubeck

et al, 2001). The questionnaire centers on three questions related to urgency and frequency and one on bladder-associated pain. It does not address generalized pelvic pain or symptomatology associated with sexual activity. This is not because these questions were not considered in the formulation of the questionnaire. Of 73 questions in the preliminary instrument covering domains of urinary symptoms, pain, sexual function, menstrual variability, and general health, only the four questions now in the instrument were needed to reliably and validly describe the illness experience of those with IC and distinguish these patients from those without the disorder (O'Leary and Sant, 1997).

Another instrument is the PUF questionnaire (Parsons et al, 2002a) (Table 14-7). It was specifically designed to include questions that directly reflect a wide variety of the symptoms experienced by patients who are affected by this disorder. One third of the questions address pelvic pain, including pain anywhere in the pelvis: the vagina, labia, lower abdomen, urethra, perineum, testes, penis, or scrotum. A large study using the PUF questionnaire has concluded that up to 23% of female Americans have BPS/IC (Parsons et al, 2002a). This makes one wary as to the usefulness and face-validity of the PUF (Ito et al, 2003). A total score of 10 to 14 indicates a 74% likelihood of a positive potassium test (PST); 15 to 19 indicates 76%; 20+ indicates 91%. To the extent that the PST is suspect, the reliability of PUF data comes into question. Question 4 of the PUF is problematic. Patients who are sexually active can gain up to 6 more points than those who are not, and

patients who over time begin sexual activity because they are feeling better can actually accumulate a falsely elevated PUF score because of this anomaly.

None of the questionnaires has been shown to be of value in diagnosis (Moldwin and Kushner, 2004), although they may suggest who should be screened further for the syndrome (Kushner and Moldwin, 2006). The O'Leary-Sant scales and University of Wisconsin instrument correlate strongly in a large population of patients with BPS/IC (Sirinian and Payne, 2001). Both the O'Leary-Sant and University of Wisconsin questionnaires are responsive to change over time and thus good for following the natural history of the disorder and the results of treatment.

Treatment outcome studies have also used the Global Response Assessment (GRA), a balanced patient self-report on overall response to therapy, developed for NIDDK-sponsored multicenter therapeutic trials (Sant et al, 2003) (Box 14-9). A one-category change in GRA correlates with a 1.2-point change in the O'Leary-Sant and a 3.1-point change in the University of Wisconsin instruments (Probert et al, 2006). More recently, the validated Genitourinary Pain Index (GUPI) has been used to assess the degree of symptoms in men and women with genitourinary complaints (Clemens et al, 2009a) (Figs. 14-12 and 14-13).

PRINCIPLES OF MANAGEMENT

The information currently available in the literature does not lend itself to easily formulating a diagnostic or treatment guideline that would be universally accepted. Different groups of experts would undoubtedly create different best practices. The algorithms for diagnosis and management constructed by the AUA (Hanno et al, 2011) and the International Consultation on Incontinence are presented in Figures 14-14 and 14-15. The compromise approach constructed by an experienced cross section of urologists and gynecologists from around the world at the International Consultation on Incontinence 2012 meeting in Paris seems reasonable and allows for significant latitude in individual practice and patient preference (Hanno et al, 2013). It is outlined in the following sections.

Definition of Bladder Pain Syndrome

(In the absence of a universally agreed-on definition, the ESSIC definition is given along with the definition of the AUA.)

ESSIC: Chronic pelvic pain, pressure, or discomfort of longer than 6 months' duration perceived to be related to the urinary

BOX 14-9 Global Response Assessment

- 3: Markedly worse
- 2: Moderately worse
- 1: Slightly worse
- 0: No change
- +1: Slightly improved
- +2: Moderately improved
- +3: Markedly improved

Data from Sant GR, Probert KJ, Hanno PM, et al. A pilot clinical trial of oral pentosan polysulfate and oral hydroxyzine in patients with interstitial cystitis. *J Urol* 2003;170(3):810-5.

bladder and accompanied by at least one other urinary symptom such as a persistent urge to void or urinary frequency. Confusable diseases as the cause of the symptoms must be excluded.

AUA guideline definition: An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than 6 weeks' duration, in the absence of infection or other identifiable causes.

Nomenclature

The scientific committee of the International Consultation voted to use the term *bladder pain syndrome* for the disorder that has been commonly referred to as *interstitial cystitis*. The term *painful bladder syndrome* was dropped from the lexicon. The term *interstitial cystitis* implies an inflammation within the wall of the urinary bladder, involving gaps or spaces in the bladder tissue. This does not accurately describe the majority of patients with this syndrome. *Painful bladder syndrome* as defined by the ICS is too restrictive for the clinical syndrome.

Properly defined, the term *bladder pain syndrome* appears to fit in well with the taxonomy of the International Association for the Study of Pain (IASP) (see later) and focuses on the actual symptom complex rather than on what appears to be a long-held misconception of the underlying pathology.

Bladder Pain Syndrome (XXIII-2) (per IASP)

BPS is the occurrence of persistent or recurrent pain perceived in the urinary bladder region and accompanied by at least one other symptom, such as pain worsening with bladder filling and daytime and/or nighttime urinary frequency. There is no proven infection or other obvious local pathology. BPS is often associated with negative cognitive, behavioral, sexual, or emotional consequences as well

Female Genitourinary Pain Index

1. In the last week, have you experienced any pain or discomfort in the following areas?

a. Entrance to vagina	<input type="checkbox"/> ₁ Yes	<input type="checkbox"/> ₀ No
b. Vagina	<input type="checkbox"/> ₁ Yes	<input type="checkbox"/> ₀ No
c. Urethra	<input type="checkbox"/> ₁ Yes	<input type="checkbox"/> ₀ No
d. Below your waist, in your pubic or bladder area	<input type="checkbox"/> ₁ Yes	<input type="checkbox"/> ₀ No

2. In the last week, have you experienced:

a. Pain or burning during urination?	<input type="checkbox"/> ₁ Yes	<input type="checkbox"/> ₀ No
b. Pain or discomfort during or after sexual intercourse?	<input type="checkbox"/> ₁ Yes	<input type="checkbox"/> ₀ No
c. Pain or discomfort as your bladder fills?	<input type="checkbox"/> ₁ Yes	<input type="checkbox"/> ₀ No
d. Pain or discomfort relieved by voiding?	<input type="checkbox"/> ₁ Yes	<input type="checkbox"/> ₀ No

3. How often have you had pain or discomfort in any of these areas over the last week?

☐₀ Never ☐₁ Rarely ☐₂ Sometimes ☐₃ Often ☐₄ Usually ☐₅ Always

4. Which number best describes your AVERAGE pain or discomfort on the days you had it, over the last week?

<input type="checkbox"/> ₀	<input type="checkbox"/> ₁	<input type="checkbox"/> ₂	<input type="checkbox"/> ₃	<input type="checkbox"/> ₄	<input type="checkbox"/> ₅	<input type="checkbox"/> ₆	<input type="checkbox"/> ₇	<input type="checkbox"/> ₈	<input type="checkbox"/> ₉	<input type="checkbox"/> ₁₀
No pain										Pain as bad as you can imagine

5. How often have you had a sensation of not emptying your bladder completely after you finished urinating, over the last week?

☐₀ Not at all ☐₁ Less than 1 time in 5 ☐₂ Less than half the time ☐₃ About half the time ☐₄ More than half the time ☐₅ Almost always

6. How often have you had to urinate again less than two hours after you finished urinating, over the last week?

☐₀ Not at all ☐₁ Less than 1 time in 5 ☐₂ Less than half the time ☐₃ About half the time ☐₄ More than half the time ☐₅ Almost always

7. How much have your symptoms kept you from doing the kinds of things you would usually do, over the last week?

☐₀ None ☐₁ Only a little ☐₂ Some ☐₃ A lot

8. How much did you think about your symptoms, over the last week?

☐₀ None ☐₁ Only a little ☐₂ Some ☐₃ A lot

9. If you were to spend the rest of your life with your symptoms just the way they have been during the last week, how would you feel about that?

<input type="checkbox"/> ₀ Delighted
<input type="checkbox"/> ₁ Pleased
<input type="checkbox"/> ₂ Mostly satisfied
<input type="checkbox"/> ₃ Mixed (about equally satisfied and dissatisfied)
<input type="checkbox"/> ₄ Mostly dissatisfied
<input type="checkbox"/> ₅ Unhappy
<input type="checkbox"/> ₆ Terrible

as with symptoms suggestive of lower urinary tract and sexual dysfunction.

History and Initial Assessment

Patients whose symptoms meet the requirements of the definition of BPS should be evaluated. The presence of commonly associated disorders including irritable bowel syndrome, chronic fatigue syndrome, and fibromyalgia in the presence of the cardinal symptoms of BPS also suggests the diagnosis. Abnormal gynecologic findings in women and well-characterized confusable diseases that may explain the symptoms must be ruled out.

The initial assessment consists of a frequency and volume chart, focused physical examination, urinalysis, and urine culture. Urine cytology, cystoscopy, and urodynamic evaluation are recommended if clinically indicated and/or the diagnosis is in doubt. Patients with urinary infection should be treated and reassessed. Those with recurrent urinary infection, abnormal urinary cytology, and microscopic or gross hematuria are evaluated with appropriate imaging and endoscopic procedures, and only if findings are unable to explain the symptoms are they diagnosed with BPS.

Initial Treatment

The initial treatment of BPS consists of the following:

- Patient education
- Dietary manipulation
- Nonprescription analgesics
- Stress reduction
- Pelvic floor relaxation techniques

In the patient with findings suggesting pelvic floor dysfunction, pelvic floor physical therapy with myofascial trigger point release and intravaginal Thiele massage is often an effective therapeutic intervention. The **treatment of pain** needs to be addressed directly, and in some instances referral to an anesthesia or pain center can be an appropriate early step in conjunction with ongoing treatment of the syndrome.

When conservative therapy fails or symptoms are severe and conservative management is unlikely to succeed, the following can be prescribed:

- Oral medication
- Intravesical treatment

It is recommended to initiate a single form of therapy and observe results, adding other modalities or substituting other

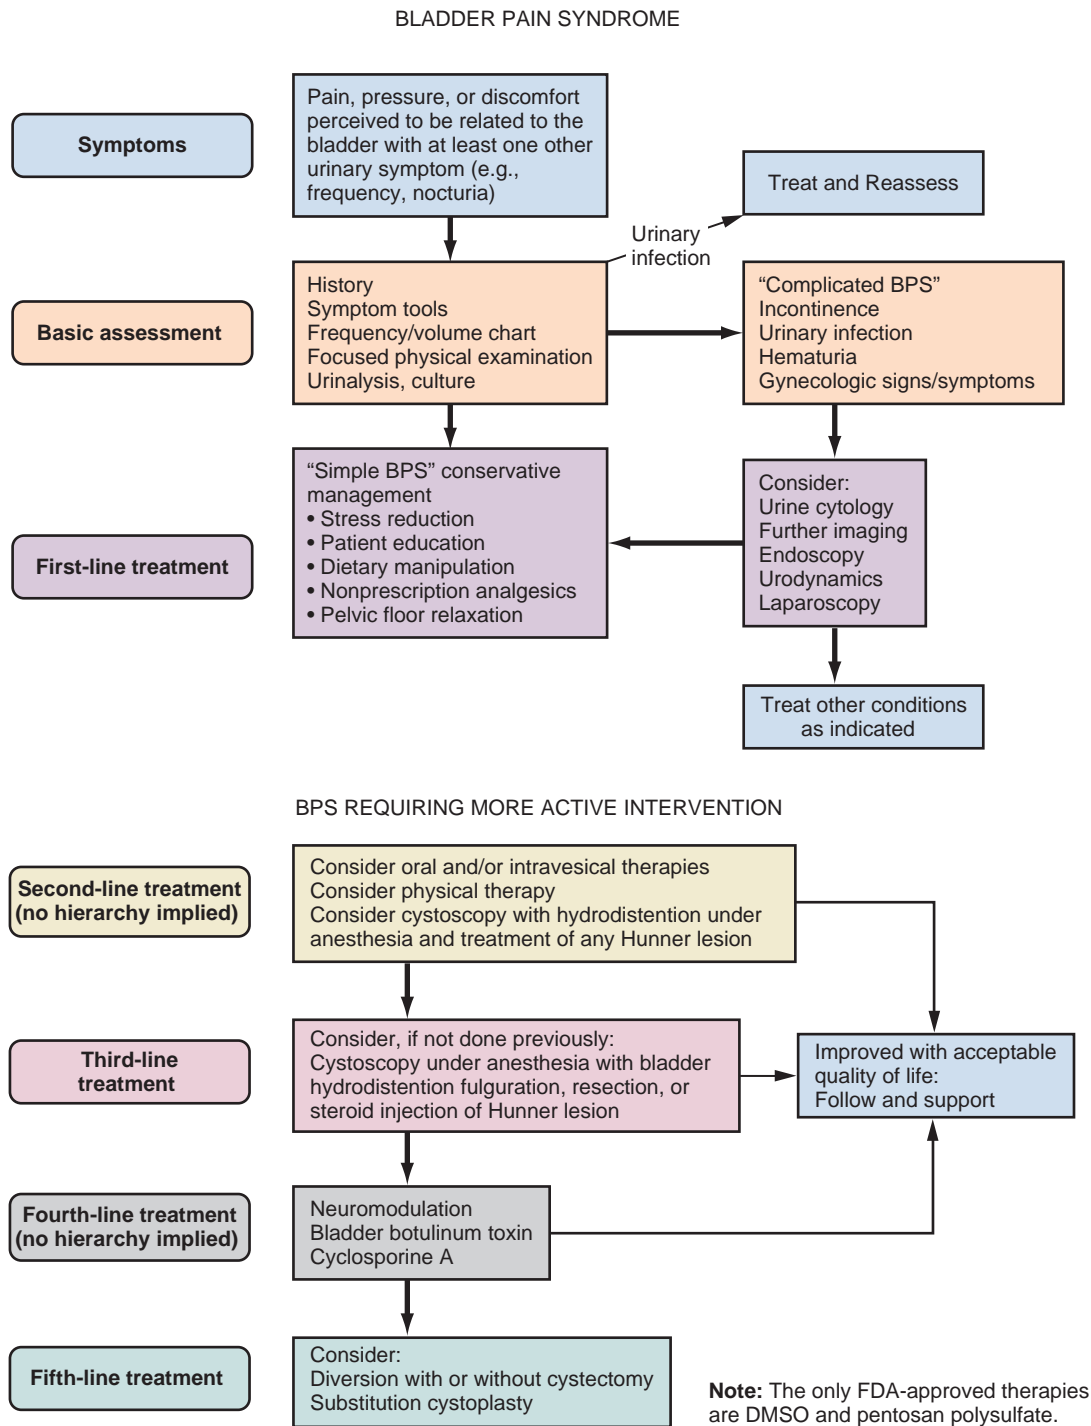

Figure 14-15. Algorithm for diagnosis and treatment of bladder pain syndrome (BPS) according to the Committee on Bladder Pain Syndrome of the Fifth International Consultation on Incontinence, held in Paris in February 2012, under the auspices of the International Consultation on Urological Diseases and enabled by the generous support of the European Association of Urology. Pain management is a primary consideration at every step of algorithm. Patient enrollment in an appropriate research trial is a reasonable option at any point. Evidence supporting neuromodulation, cyclosporine A, and botulinum toxin for BPS indication is limited. These interventions are appropriate only for practitioners with experience treating BPS and willingness to provide long-term care postintervention. DMSO, dimethyl sulfoxide; FDA, U.S. Food and Drug Administration. (From Hanno P, Dinis P, Lin A, et al. Bladder pain syndrome. In: Abrams P, Cardozo L, Khoury S, et al, editors. Incontinence. Paris: International Consultation on Urological Diseases/European Association of Urology; 2013. p. 1583–649.)

modalities as indicated by degree of response or lack of response to treatment.

Secondary Assessment

If initial oral or intravesical therapy fails, or before beginning such therapy based on clinician judgment, it is reasonable to consider further evaluation, which can include urodynamics, pelvic imaging, and cystoscopy with bladder distention and possible bladder biopsy under anesthesia.

- Findings of bladder overactivity suggest a trial of antimuscarinic therapy.
- The presence of a Hunner lesion suggests therapy with transurethral resection, fulguration of the lesion, or direct steroid injection into the lesion.
- Distention itself can have therapeutic benefit in 30% to 50% of patients, though benefits rarely persist for longer than a few months.
- Grade of recommendation: C

Refractory Bladder Pain Syndrome

Patients with persistent, unacceptable symptoms despite oral and/or intravesical therapy are candidates for more aggressive modalities. Many of these are best administered within the context of a clinical trial if possible. These may include the following:

1. Neuromodulation
2. Intradetrusor BTX
3. Oral cyclosporine A
4. Clinical trials of newly described pharmacologic management techniques

At this point, most patients will benefit from the expertise of an anesthesia pain clinic.

The last step in treatment is usually some type of surgical intervention aimed at increasing the functional capacity of the bladder or diverting the urinary stream.

- Urinary diversion with or without cystectomy has been used as a last resort with good results in selected patients.
- Augmentation or substitution cystoplasty seems less effective and more prone to recurrence of chronic pain in small reported series.

Philosophy of Management

I believe that, because of the natural history of the disorder, it is best to cautiously progress through a variety of treatments. Whereas the shotgun approach, starting newly diagnosed patients on a variety of simultaneous medications, seems to have many adherents, employing one treatment at a time makes the natural history of the disease itself an ally in the treatment process. One should encourage patients to maximize their activity and live as normal a life as possible, rather than becoming prisoners of the condition. Although some activities or foods may aggravate symptoms, nothing has been shown to negatively affect the disease process itself. Therefore patients should feel free to experiment and judge for themselves how to modify their lifestyle without the guilt that comes from feeling they have harmed themselves if symptoms flare.

Dogmatic restriction and diet are to be avoided unless they are shown to improve symptoms in a particular patient.

In the near future, phenotyping of patients with BPS/IC may improve treatment outcomes, but only time and future studies will determine if this is true (Baranowski et al, 2008). Foundational manuscripts from the MAPP Research Network (mappnetwork.org), an 11-year effort of the NIDDK, are in final preparation for submission in 2014 and underlie this massive effort, which will help to answer the phenotyping question (Clemens et al, 2014a, 2014b; Krieger et al, 2014; Landis et al, 2014). To answer the perennial query, "Can we, as health care providers, make evidence-based decisions for BPS/IC at this time?" the answer has not changed since the last edition of this text: *Sometimes* (Fall et al, 2008).

Epidemiology of Sexually Transmitted Diseases

Urethritis

Epididymitis

Genital Ulcers

Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome and the Urologist

EPIDEMIOLOGY OF SEXUALLY TRANSMITTED DISEASES

The Centers for Disease Control and Prevention (CDC) publishes annual reports on the number of cases of sexually transmitted diseases (STDs) in the United States (CDC, 2013). Data from 2012 are summarized in Tables 15-1 and 15-2. Overall, the estimate is that nearly 20 million new STDs occur every year in the United States, half among people aged 15 to 24 years. This group accounted for 58% of gonorrhea and 69% of chlamydia cases in 2012. Another group with disproportionate risk is men who have sex with men (MSM). This group now accounts for 75% of all primary and secondary syphilis cases. Factors that increase the risk of acquiring an STD include a higher number of lifetime sex partners, unprotected sex without use of a condom, risky sex partners, and the effect of alcohol or drugs on sexual decision making (Pollack et al, 2013).

Centers for Disease Control and Prevention Screening Recommendations

1. Annual chlamydia screening for all sexually active women age 25 and younger, as well as for women with risk factors such as new or multiple sex partners.
2. Annual gonorrhea screening for at-risk sexually active women, including women with new or multiple sex partners, or women who are living in areas with high rates of disease.
3. Syphilis, human immunodeficiency virus (HIV), and chlamydia screening for all pregnant women, and gonorrhea screening for at-risk pregnant women starting early in pregnancy, with repeat testing as needed.
4. At least once-per-year screening for syphilis, chlamydia, gonorrhea, and HIV for all sexually active gay, bisexual, and other MSM. Men who have multiple or anonymous partners should be screened more frequently for STDs, at 3- to 6-month intervals. More frequent screening is also recommended for MSM who use illicit drugs, particularly methamphetamine, or whose sex partners use them.

*The Centers for Disease Control and Prevention (CDC) provides national guidelines on the diagnosis and treatment of sexually transmitted diseases. The 2010 guidelines were used at the time this chapter was written (CDC, 2010c). These guidelines are periodically updated based on review of the most recent literature, and the reader is encouraged to check for updates from the CDC before treating patients with sexually transmitted diseases. Guidelines also include instructions for partner treatment and recommendations on follow-up.

Diseases That Must Be Reported to Local Health Authorities

Syphilis, gonorrhea, chlamydia, chancroid, HIV infection, and acquired immunodeficiency syndrome (AIDS) are reportable diseases in every state. Check requirements for reporting other STDs by state.

URETHRITIS

Urethritis, or urethral inflammation, can be the result of STDs. Symptoms include urethral discharge, pruritus, and dysuria. Several organisms can cause urethritis. Two broad classes are gonococcal urethritis (GU), caused by *Neisseria gonorrhoeae*, and nongonococcal urethritis (NGU), caused by all other organisms.

Diagnosis

Traditionally, urethritis is documented based on examination of the purulent discharge with Gram stain showing more than 5 white blood cells (WBCs) per high-power field (HPF), and documenting the presence or absence of white cells with intracellular gram-negative diplococci indicating GU. Looking at the urethral fluid can yield false-negative results, with reported sensitivity for more than 5 WBCs/HPF as low as 29% for chlamydial infection (Janier et al, 1995). Another criterion is a positive leukocyte esterase test result on first void urine or microscopic examination of first void urine sediment demonstrating more than 10 WBCs/HPF (CDC, 2010c). Nucleic acid amplification tests (NAATs) performed on urine can be used to look for *N. gonorrhoeae* and *Chlamydia trachomatis* (Geisler et al, 2005). Culture and hybridization tests that require urethral swab specimens are available. However, NAATs are preferred because of their higher sensitivity (Geisler, 2011), and urethral swabs are no longer recommended for evaluation of urethritis. All patients should be tested for both gonorrhea and chlamydia, given the high association of coinfection.

Gonococcal Infections

Neisseria gonorrhoeae is a gram-negative diplococcus. It is the second most common bacterial cause of STDs in the United States (CDC, 2013). The incubation period ranges from 3 to 14 days. Men will usually have symptoms that cause them to seek treatment soon enough to prevent transmission to others. This could include urethritis, epididymitis, proctitis or prostatitis. Women are frequently asymptomatic. Complications in women include pelvic inflammatory disease (PID), tubal scarring, infertility, ectopic pregnancy, and chronic pelvic pain (Short et al, 2009). Disseminated gonorrhea is rare today but can produce arthritis, dermatitis, meningitis, and

TABLE 15-1 Sexually Transmitted Disease Cases, 2012, Reported per 100,000 Population

	CASES REPORTED, 2012	RATE PER 100,000 PEOPLE	NOTES ON CHANGES
Chlamydia	1,422,976	456.7	Stable since 2011
Gonorrhea	334, 826	107.5	4.1% increase since 2011
Syphilis, primary and secondary	15, 667	5.0	11.1% increase since 2011
Chancroid	15		Decline 1987- 2001, steady fluctuation since then

TABLE 15-2 Sexually Transmitted Disease Cases, 2012, Reported by Initial Visits to Physicians' Offices

SEXUALLY TRANSMITTED DISEASE	NUMBER OF CASES REPORTED DURING INITIAL VISITS TO PHYSICIANS' OFFICES
Genital herpes	228,000
Genital warts	353,000
Vaginal trichomoniasis	219,000
Other vaginitis	3,452,000

endocarditis. Gonorrheal infection can also increase the risk of contracting and transmitting HIV (Cohen et al, 1997).

Treatment

Dual therapy is required for both *N. gonorrhoeae* and chlamydia because of the high rate of coinfection. Gonorrhea treatment is hindered by the ability of gonorrhea to develop antimicrobial resistance. As of 2007, quinolones are no longer recommended in the United States for treatment of gonorrhea and associated conditions such as PID (CDC, 2007). As of August 2012, because of high resistance, cefixime is no longer recommended as first-line therapy to treat gonorrhea (CDC, 2012; Kirkcaldy et al, 2013). Current treatment of uncomplicated gonococcal infections of the cervix, urethra, and rectum involves ceftriaxone 250 mg IM single dose plus azithromycin 1 gm orally in a single dose or doxycycline 100 mg orally twice per day for 7 days. Because NAATs cannot provide susceptibility results, in cases of treatment failure a culture test should be performed along with antimicrobial susceptibility testing. All persons with gonorrhea should be tested for other STDs including chlamydia, syphilis, and HIV. Treatment is no different in persons with HIV. In persons with a history of penicillin allergy, third-generation cephalosporins have a low incidence of cross-reactivity, lower than the 5% to 10% in first-generation cephalosporins.

Nongonococcal Urethritis

Chlamydia trachomatis accounts for 15% to 40% of cases of NGU, with less common causes including *Mycoplasma genitalium* (15% to 25%), *Trichomonas vaginalis*, adenoviruses, and herpes simplex virus type 1 (HSV-1); a pathogen is not identified in 20% to 50% of cases (Deguchi and Maeda, 2002; Bradshaw et al, 2006; Tabrizi et al,

2007). HSV-1 urethritis may be associated with oral sex (Bradshaw et al, 2006).

Chlamydia

Chlamydia is the most common bacterial sexually transmitted STD in the United States. The 1,422,976 cases of *C. trachomatis* infection reported to the CDC in 2012 comprised the largest number of cases ever reported to the CDC for any condition (CDC, 2013). The incubation period ranges from 3 to 14 days. The prevalence of chlamydia is highest in persons 25 years of age or older (Geisler, 2011). Other sequelae of chlamydial infection in males include epididymitis and Reiter syndrome (Geisler et al, 2008). One of the main concerns with untreated chlamydial infections in men is transmission to their female partners (Geisler, 2011). Up to 75% of women with chlamydial infection can be asymptomatic. Ascending chlamydial infection can result in scarring of the fallopian tubes, PID, risk for ectopic pregnancy, pelvic pain, and infertility. The risk of untreated chlamydial infection producing PID is estimated to be between 9.5% and 27% (Gottlieb et al, 2013).

Mycoplasma genitalium and Ureaplasma

Mycoplasmas are the smallest prokaryotes capable of autonomous replication. The genus *Mycoplasma* belongs to the class Mollicutes, along with *Ureaplasma*. Mycoplasmas lack a cell wall and cannot be Gram stained. They contain a terminal adhesion structure that helps them attach to epithelial cells (Cazanave et al, 2012). *M. genitalium* was first described as a pathogen in urethritis in 1980, and considerable evidence since has established this organism as a cause of acute NGU (Manhart et al, 2011). Most infected patients are symptomatic, but approximately 25% may have asymptomatic urethral infection (Taylor-Robinson and Jensen, 2011). *M. genitalium* can become intracellular, which can establish a chronic infection and aid in avoidance of both immune response and antibiotics (McGowin et al, 2009). The prevalence of *M. genitalium* in chronic urethritis is estimated at 12% to 41% (Manhart et al, 2011). Risk factors for infection with *M. genitalium* in men are young age, sexual intercourse in the past month, and a sex partner with a recent history of STD diagnosis or treatment (Mena et al, 2002). Culture is very difficult, and the diagnosis is made by nuclear amplification or polymerase chain reaction (PCR), but no commercially available test is available (Cazanave et al, 2012; Sena et al, 2012).

Other species of Mollicutes include *Ureaplasma urealyticum* and *Ureaplasma parvum* (Cazanave et al, 2012). The evidence for *Ureaplasma* as a causative agent in NGU is conflicting (Taylor-Robinson et al, 1979). In a case control study of 329 men with symptoms of urethritis and controls without symptoms, both *U. urealyticum* and *U. parvum* were found more often in controls than in cases and therefore were not considered to be associated with NGU in this population (Bradshaw et al, 2006). A more recent series reported *U. urealyticum* in 24% of cases of NGU (Wetmore et al, 2011a). An explanation for the difference among numerous studies has been proposed by Wetmore and colleagues (2011b). In a case control series of men with clinical signs and symptoms of NGU and controls from an STD clinic or emergency room, the overall association of *U. urealyticum* and NGU was marginal, and *U. parvum* was not associated with NGU. However, in men with fewer than 10 lifetime vaginal sex partners, *U. urealyticum* was significantly associated with NGU. The hypothesis proposed is that adaptive immunity by repeated or prolonged exposure to *U. urealyticum* through multiple sex partners may result in asymptomatic infection without signs of urethral inflammation.

Trichomonas

Trichomonas vaginalis is a flagellated parasite that exclusively infects the urinary tract (Muzny and Schwebke, 2013). *T. vaginalis* is a common vaginal pathogen but also can cause urethritis in men. Among men attending an STD clinic, the prevalence is reported at

3% to 17% (Schwebke and Hook, 2003; Bachmann et al, 2011). Wet mounts examined for *T. vaginalis* have been traditionally used for diagnosis, with a sensitivity of only 60%; culture has also been used as the gold standard of diagnosis. Both are being supplanted by NAATs (Schwebke et al, 2011).

Treatment of Nongonococcal Urethritis

Patients are treated initially for both *N. gonorrhoeae* and chlamydia. Treatment is azithromycin 1 g orally as a single dose or doxycycline 100 mg orally twice per day for 7 days.

Recurrent and Persistent Urethritis

Persons who were noncompliant with the initial regimen or reexposed to an untreated sex partner can be treated again with the initial medications. Persistent symptoms after doxycycline treatment could be caused by doxycycline-resistant *M. genitalium*, or by *T. vaginalis*. A urine specimen can be sent for testing (Schwebke and Hook, 2003). Alternative regimens include metronidazole 2 g orally in a single dose or tinidazole 2 g orally in a single dose plus azithromycin 1 g orally in single dose (if not used in initial episode). Another choice for second-line therapy is moxifloxacin 400 mg orally for 7 days, which is effective against *M. genitalium* (Bradshaw et al, 2008). The resistance rate for *M. genitalium* to azithromycin has been reported at 16% to 24% (Bradshaw et al, 2008; Twin et al, 2012). In men with persistent symptoms, urologic evaluation does not usually identify a specific cause for the urethritis. One consideration is to make sure there is not pain elsewhere in the pelvis, which could indicate chronic pelvic pain syndrome as opposed to localized urethritis (Nickel et al, 2003).

EPIDIDYMITIS

Acute epididymitis is characterized by pain, swelling, and inflammation of the epididymis that lasts less than 6 weeks (Tracy et al, 2008). The testis is usually involved (epididymo-orchitis). Among sexually active men younger than 35 years, acute epididymitis is frequently caused by *C. trachomatis* or *N. gonorrhoeae*. Among MSM, acute epididymitis can be caused by enteric organisms such as *Escherichia coli* and *Pseudomonas* as a result of anal intercourse. Sexually transmitted acute epididymitis is usually also accompanied by urethritis, although this can be asymptomatic. In men older than 35 years, a sexually transmitted cause is uncommon, and the infecting organism is usually associated with bacteriuria from obstruction or benign prostatic hyperplasia (BPH), with *E. coli* the most common organism (Berger et al, 1979). There can be atypical organisms in men with HIV, including cytomegalovirus (CMV), *Salmonella*, *Ureaplasma*, *Corynebacterium*, *Mycoplasma*, and fungi (Parr et al, 1993; Hohmann, 2001). Chronic epididymitis is characterized by more than 6 weeks of pain in the scrotum, testicle, and epididymis. Chronic infectious epididymitis is most commonly seen with tuberculosis (TB), as a consequence of hematogenous spread rather than seeding of the urinary tract from the kidneys (Heaton et al, 1989).

The diagnosis of acute epididymitis includes ruling out testicular torsion, especially in younger patients. Scrotal ultrasonography can be helpful but is not always diagnostic (Pontari, 2013). The evaluation of acute epididymitis should include either a Gram stain of urethral secretions as noted earlier for urethritis, a urine dip for leukocyte esterase on first-void urine, or microscopic examination of the first-void urine demonstrating more than 10 WBCs/HPF. Urine can be sent for NAAT (CDC, 2010c). Empirical therapy is indicated before laboratory test results are available. First-line therapy in men younger than 35 years is ceftriaxone 250 mg IM plus doxycycline 100 mg orally twice per day for 10 days. For patients with suspected enteric organisms, treatment is ceftriaxone plus levofloxacin 500 mg orally twice per day for 10 days (CDC, 2010c).

GENITAL ULCERS

In the United States, most young sexually active patients who have ulcers (Table 15-3) have either genital herpes or syphilis, with genital herpes being more common. Less common causes are chancroid and donovanosis. Ulcers may also be associated with noninfectious causes such as yeast, trauma, malignancy, aphthae, fixed drug eruption, and psoriasis (CDC, 2010c). In addition to a history and physical examination, all patients with ulcers need serologic testing for syphilis and a darkfield examination if possible, culture or PCR testing for HSV, and diagnostic serology for determining the specific type of HSV. In environments where chancroid is prevalent, a test for *Haemophilus ducreyi* should be performed. Patients who are not known to be HIV positive should be tested for HIV. Even after complete diagnostic evaluation, 25% of patients with genital ulcers will have no laboratory-confirmed diagnosis. Biopsy of ulcers is indicated if they are unusual or do not respond to initial therapy.

Syphilis

Syphilis is caused by *Treponema pallidum*, a coiled spirochete bacterium. *Treponema pallidum* cannot be easily cultured. Transmission is usually by sexual contact, through microabrasions in skin and mucosal membranes in patients with primary and secondary syphilis (Ho and Lukehart, 2011). The risk increases with increasing numbers of sexual partners (French, 2007). Syphilis replicates at the site of the infection and divides every 30 to 33 hours (Fieldsteel et al, 1981). It is estimated that 50% to 60% of sexual contacts of individuals with early syphilis will acquire syphilis (Schober et al, 1983).

Primary Syphilis

The lesions occur at the initial site of infection. The incubation is typically 2 to 3 weeks but can range from 9 to 90 days for the appearance of lesions after infection (French, 2007). The lesions are usually single and painless but can be multiple, and up to one quarter of chancres can be painful (Read and Donovan, 2012). Local nontender lymphadenopathy is common. Untreated lesions heal spontaneously in 3 to 8 weeks (Ho and Lukehart, 2011). In men,

TABLE 15-3 Genital Ulcer Disease

DISEASE	LESIONS	LYMPHADENOPATHY	SYSTEMIC SYMPTOMS
Primary syphilis	Painless , indurated, with a clean base, usually singular	Nontender, rubbery, nonsuppurative bilateral lymphadenopathy	None
Genital herpes	Painful vesicles, shallow, usually multiple	Tender, bilateral inguinal adenopathy	Present during primary infection
Chancroid	Tender papule, then painful , undermined purulent ulcer, single or multiple	Tender, regional, painful, suppurative nodes	None
Lymphogranuloma	Small, painless vesicle or papule progresses to an ulcer	Painful, matted, large nodes with fistulous tracts	Present after genital lesion heals

Figure 15-1. Syphilis with penile chancre.

Figure 15-2. Syphilis with vulvar chancre.

lesions are typically on the glans or the coronal or perineal area (Fig. 15-1), and on the labia or perianal area in women (Fig. 15-2).

Secondary Syphilis

Treponema pallidum eventually becomes a systemic infection with bacteremia. Secondary syphilis appears 3 to 5 months after the

Figure 15-3. Secondary syphilis affecting the soles of the feet.

initial infection and is characterized by a maculopapular rash, which is often widespread and involves the scalp, palms, and soles of the feet in 75% of patients (Fig. 15-3) (Read and Donovan, 2012). The rash can ulcerate and lead to condyloma lata, which are wartlike lesions. Additional symptoms include fever, malaise, weight loss, patchy alopecia, and ocular inflammation (Mindel et al, 1989). There is also a broad vasculitis that in approximately 10% of patients may manifest as hepatitis, iritis, nephritis, and neurologic problems including headache and cranial nerve involvement, especially VIII (auditory). Relapses usually occur in the first year after infection and rarely after the second year. The infection then becomes latent and asymptomatic.

Latent Syphilis

Latent syphilis is defined as seroreactivity with no clinical evidence of disease and is arbitrarily divided into early and late latent infection. To be diagnosed with early latent syphilis, the patient must have no signs of primary or secondary disease and have positive syphilis serology, preceded by negative serology in the past year, or recent contact with an infectious patient (CDC, 2010c). Asymptomatic patients with no evidence of recent negative serology or previous treatment are classified as having syphilis of unknown duration and are considered to have late latent syphilis (Read and Donovan, 2012).

Tertiary or Late Syphilis

About 35% of individuals with late latent syphilis will develop the late manifestations of syphilis, which include neurosyphilis, cardiovascular syphilis, and gummatous syphilis. These are rare outside of developing countries. Neurosyphilis can be seen in secondary syphilis, and meningovascular syphilis also occurs in tertiary syphilis. The incubation period is usually 5 to 12 years. After 10 to 20 years, the spinal column and brain can also be involved. The spinal cord syndrome is called *tabes dorsalis*, and the brain syndrome is also called *general paralysis of the insane* (Danielsen et al, 2004;

French, 2007). Cardiovascular syphilis occurs 15 to 30 years after infection and may occur in any large vessel (French, 2007).

Tests for Syphilis

Darkfield Examination. Cultures of *T. pallidum* are not possible in vitro. Direct tests include identification of *T. pallidum* under a dark-ground microscope from samples taken from a lesion, with a sensitivity rate of up to 97% (Wheeler et al, 2004). This, however, requires trained personnel.

Serology

Nontreponemal Tests. Measurement of antibodies is important for the screening and diagnosis of syphilis. There are two categories of tests: nontreponemal, which are directed against phospholipids, and treponemal, which are directed against *T. pallidum* polypeptides. Nontreponemal antibodies bind lipids that have bound to the treponeme and become antigenic (Lafond and Lukehart, 2006). Nontreponemal antibodies are detected with the rapid plasma reagin (RPR) test, the Venereal Disease Research Laboratory (VDRL) test, and the toluidine red unheated serum test (TRUST). Results are positive within 21 days but sometimes as long as 6 weeks after infection. They are universally positive in secondary syphilis (Read and Donovan, 2012). Nontreponemal test results need confirmation with a treponemal test because they can be positive in other conditions such as viral infections, pregnancy, malignancies, autoimmune disease, and advanced age (Larsen et al, 1995). False-negative reactions occur if there is an excess of antibodies that overwhelm the assay, called the *prozone effect* (CDC, 2010c). Nontreponemal tests are used to monitor disease activity. A fourfold change in titer equivalent to a change of two dilutions (e.g., from 1:16 to 1:4) is considered necessary to demonstrate a clinically significant difference. The same test should be used in a given person because the tests are not directly comparable (CDC, 2010c). Nontreponemal tests usually become nonreactive with time after treatment, but in some patients levels of the antibodies can persist for a long time, including for the lifetime, a response referred to as the *serofast reaction* (CDC, 2010c).

Treponemal Tests. Treponemal antibodies are detected by immunofluorescence in the fluorescent treponemal antibody absorption (FTA-ABS) test or by agglutination in the microhemagglutination assay for *T. pallidum* (MHA-TP), the *T. pallidum* hemagglutination assay (TPHA), or the *T. pallidum* particle agglutination (TP-PA) test. False-positive results are uncommon but can occur in patients with collagen disease, systemic lupus erythematosus, and other infections (Hart, 1986). Treponemal test results remain positive for life except in 15% to 25% of patients treated early for primary syphilis (Young et al, 2009). Treponemal tests are not used to determine disease activity or treatment response.

Other Tests. Polymer chain reaction to identify *T. pallidum* may prove to be useful, with a sensitivity of 94.7% and specificity of 98.6% reported (Palmer et al, 2003). Rapid syphilis tests including enzyme-linked immunosorbent assays (ELISAs) are also available and are U.S. Food and Drug Administration (FDA) approved and cheaper than the nontreponemal tests usually used for initial diagnosis. They can give results in 5 to 20 minutes but cannot distinguish between active and treated syphilis (Ho and Lukehart, 2011). A newer paradigm of testing is to use the rapid test first, and if the result is positive, to perform a nontreponemal test with titers to guide management. If the nontreponemal test result is negative, a different treponemal test should be performed.

Coinfection with Human Immunodeficiency Virus

Of patients becoming infected with syphilis, up to 25% are HIV infected, and the incidence rate for syphilis in HIV patients has been reported as 77 times that of the general population (Chesson et al, 2005). The clinical course of syphilis in a person with HIV is similar to that in immunocompetent persons. However, HIV-positive patients may have larger ulcers in the primary phase and may be at risk for a more rapid progression to neurosyphilis with a CD4 count

of 350 or lower and/or a nontreponemal serologic test result of 1:32 or higher (French, 2007). Occasionally an unusual serologic response may occur with a false-negative result. If the clinical course strongly suggests syphilis and serologic test results are negative, consider other tests such as biopsy of lesion or rash (CDC, 2010c). All patients with syphilis should be tested for HIV.

Treatment of Syphilis

The standard treatment for all stages of syphilis is penicillin G. The stage and clinical manifestations of syphilis determine the preparation, dosage, and length of treatment. Treatment guidelines from the CDC are presented in Table 15-4 (CDC, 2010c). Not considered appropriate treatment are combinations of benzathine and procaine penicillin (Bicillin C-R), nor is oral penicillin. Patients with HIV receive the same treatment regimen as non-HIV-infected persons. A reaction consisting of fever, malaise, nausea, and vomiting, called the Jarisch-Herxheimer reaction, can occur. This is not an allergic reaction to penicillin but occurs with treatment of the treponemes, and more commonly with treatment with penicillin and in early syphilis. It may also be associated with chills and exacerbation of secondary rash. Treatment is with bed rest and nonsteroidal anti-inflammatory medications. Signs of treatment failure include persistent or recurring signs and symptoms of syphilis, and sustained fourfold increase in

TABLE 15-4 Treatment of Syphilis (Centers for Disease Control and Prevention 2010 Guidelines for Treatment of Sexually Transmitted Diseases)

STAGE OF SYPHILIS	PENICILLIN TREATMENT	PENICILLIN-ALLERGIC PATIENTS
Primary, secondary, and early latent syphilis, no neurologic involvement	Benzathine penicillin G 2.4 million units IM, single dose	Doxycycline 100 mg PO bid for 2 wk Tetracycline 500 mg PO qid for 2 wk
Late latent or latent syphilis of unknown duration, no neurologic involvement	Benzathine penicillin G 2.4 million units IM once per week for 3 wk	Doxycycline 100 mg PO bid for 28 days Tetracycline 500 mg PO qid for 28 days
Tertiary (late) syphilis without neurologic involvement	Benzathine penicillin G 2.4 million units IM once per week for 3 wk	Consult infectious disease specialist
Neurosyphilis Alternative regimen	Aqueous crystalline penicillin G 3-4 million units IV q4h, or continuous IV infusion for total 18-24 million units per day, for 10-14 days Procaine penicillin 2.4 million units IM daily plus probenecid 500 mg PO qid, both for 10-14 days	

nontreponemal test result or failure to decrease fourfold within 6 months of therapy. Patients should be (1) retested for HIV, (2) evaluated for neurosyphilis with cerebrospinal fluid (CSF) examination, and (3) re-treated with weekly injections of benzathine penicillin G, 2.4 million units IM for 3 weeks, unless neurosyphilis is diagnosed.

Herpes

Herpes simplex virus type 1 and HSV-2 are double-stranded DNA viruses. They share 83% sequence homology of their protein coding regions and share similar structure of their genomes (Gupta et al, 2007). They can be distinguished serologically. HSV-1 causes mainly oral infections but now accounts also for at least half of first episodes of genital HSV infections (Roberts et al, 2003). This is thought to be a combination of later acquisition of oral HSV-1, which would confer immunity to the genital infection, and increase in oral sex in young adults (Halpern-Felsher et al, 2005). HSV-2 causes genital herpes and is transmitted by sexual contact. Women are more susceptible to HSV-2 infection than men and are more likely to have symptomatic infections (Langenberg et al, 1999). Most HSV-2 transmission thus occurs from individuals who do not know they are infected (Mertz, 2008). In a study of 5452 adults attending primary care offices in the United States, the seroprevalence of HSV-2 was 25.5%, but only 12% of these patients reported a history of prior infection (Leone et al, 2004). HSV-2 infection seems to protect against HSV-1 infection, but HSV-1 gives only a small amount of protection from infection with HSV-2 (Looker and Garnett, 2005).

Pathophysiology

Herpes simplex virus initiates replication in epithelial cells at the site of entry, damages the cells, and enters the ends of peripheral sensory nerves. It is then transported in a retrograde manner to the cell body in the sensory root ganglia. In the initial infection, herpes also spreads to the local and regional lymph nodes. Once in the nerve cell body, HSV enters a latent state (Jerome et al, 1998). Recurrence and reactivation of virus occur with transportation in the peripheral nerves back to the mucosal or skin surface. Events that trigger reactivation of HSV include local trauma such as surgery or ultraviolet light, immunosuppression, or fever (Gupta et al, 2007). Recurrence can lead to recurrence of lesions from mucosal or skin disruption or may occur in the absence of recognizable lesions. This is termed *asymptomatic* or *subclinical shedding* (Wald et al, 1995; Wald et al, 2000).

Natural History and Diagnosis

The classic first presentation of primary herpes is clusters of erythematous papules and vesicles on the external genitalia that do not follow a neural distribution (Figs. 15-4 and 15-5). This usually occurs 4 to 7 days after sexual intercourse (Looker and Garnett, 2005). Many herpetic lesions do not have the classic appearance and may look like fissures or furuncles, and in women may manifest as vulvar erythema (Koutsky et al, 1992). Patients have pain, burning, or itching, and 80% of women report dysuria. Other associated symptoms include fever, headache, malaise, and myalgias (Corey et al, 1983). Tender inguinal and femoral lymph nodes may be present. Primary genital HSV-1 infection cannot be distinguished from HSV-2 infection on clinical examination alone, but requires laboratory testing. Over the next 2 to 3 weeks, 75% of patients have new lesions, which can progress to vesicles and pustules and can coalesce into ulcers before crusting and healing (Corey et al, 1983). Possible complications include aseptic meningitis and autonomic dysfunction that can lead to urinary retention (Corey et al, 1983).

Recurrent Episodes

A primary genital herpes infection with either HSV-1 or HSV-2 is more severe in the absence of preexisting HSV-1 immunity (Corey

Figure 15-4. Herpes simplex virus infection on the penis.

Figure 15-5. Typical vesicular eruption of herpes simplex virus.

et al, 1983). Subsequent recurrent episodes with established immunity are milder than the initial infection. Genital HSV-1 recurs much less frequently (0.02 recurrences per month) than genital HSV-2 infections (0.23 recurrences per month), on the order of 10-fold less (Lafferty et al, 1987a). Although shedding is greatest in the first 6 to 12 months, it can continue for years (Schacker et al, 1998; Benedetti et al, 1999). Lesions heal in 5 to 10 days in the absence of antiviral treatment. HSV recurrences decrease after the first year, although some spike in recurrences in HSV-2 even after 4 years of follow-up have been noted (Benedetti et al, 1999).

Diagnosis and Testing for Herpes Simplex Virus

A definitive diagnosis of HSV subtype should be made both to confirm the diagnosis and to obtain important prognostic

TABLE 15-5 Recommended Oral Treatment for Genital Herpes Simplex Virus Infection

AGENT	FIRST CLINICAL EPISODE	EPISODIC THERAPY	SUPPRESSIVE THERAPY
Acyclovir	400 mg tid for 7-10 days or 200 mg 5 times/day for 7-10 days	400 mg tid for 5 days or 800 mg tid for 2 days or 800 mg bid for 5 days	400 mg bid
Famciclovir	250 mg bid for 7-10 days	125 mg bid for 5 days or 1000 mg bid for 1 day or 500 mg once, followed by 250 mg bid for 2 days	250 mg bid
Valacyclovir	1 g bid for 7-10 days	500 mg bid for 3 days or 1 g sid for 5 days	500 mg sid or 1 g sid

Modified from Workowski KA, Berman S; Centers for Disease Control and Prevention (CDC). Sexually transmitted diseases treatment guidelines, 2010. MMWR Recomm Rep 2010;59(RR-12):1–110.

information, given the clinical disparity between genital HSV-1 and HSV-2. In patients with lesions, fluid can be obtained from the base of the genital lesion and sent for viral culture, HSV antigen detection, or PCR of HSV DNA (Rose et al, 2008; Nguyen et al, 2010). The detection rate for HSV from lesions is 80% for primary infections but only 25% to 50% for recurrent lesions, and even less if the lesion has begun to heal (Lafferty et al, 1987b). In patients with no active lesions, serology must be used—that is, testing for antibodies. Specific immunoglobulin G (IgG) testing for glycoprotein G of HSV-1 or HSV-2 can distinguish the two types of HSV (Ashley, 2001). Serology is recommended for confirmation of a clinical diagnosis of genital herpes in patients with recurrent genital symptoms, atypical lesions, or healing ulcers and negative viral cultures. Type-specific antibodies to herpesvirus can take from 2 weeks to 3 months to develop; thus in a person with newly acquired herpes, an initial negative serology followed by a positive test after 12 weeks confirms a new infection (CDC, 2010c).

Treatment (Table 15-5)

Currently available medications to treat herpes do not eradicate the virus, but aim to reduce the signs and symptoms of infection and to prevent new lesions. Available drugs include acyclovir (intravenous only), valacyclovir, and famciclovir (CDC, 2010c). Treatment for a first clinical episode should be started on clinical grounds before laboratory confirmation of diagnosis. Treatment is usually 7 to 10 days but should be extended if lesions are not adequately healed (CDC, 2010c). Intravenous acyclovir (5 to 10 mg/kg every 8 hours) may be needed for those with neurologic complications, those unable to take oral medications, or those with widespread disease (e.g., immunocompromised patients) (Gupta et al, 2007). Treatment of recurrent episodes reduces their severity and duration. Oral therapy within 24 hours of the first signs or symptoms of recurrence increases the chance of resolving a recurrence without lesions (Leone et al, 2002; Wald et al, 2002; Aoki et al, 2006). In patients with frequent recurrences, daily suppressive therapy can be used to reduce recurrences by 70% to 80% (Wald et al, 2006). Patients with HIV can have prolonged or severe episodes of HSV infection, and HSV shedding is increased in HIV-infected persons. Doses and durations of medications are increased for suppression and treatment of episodic HSV infections in persons with HIV (CDC, 2010c).

Chancroid

Chancroid is caused by the gram-negative bacterium *H. ducreyi* (Lewis, 2003). Infection leads to anogenital ulceration and lymphadenitis with progression to bubo formation (Lewis and Ison, 2006). The incubation period is 3 to 10 days, with the initial

Figure 15-6. Chancroid with regional adenopathy.

presentation of a papule that may progress to form an ulcer (Fig. 15-6) (Lewis and Ison, 2006). Circumcised men are at lower risk of being infected with chancroid (Weiss et al, 2006). The prevalence of chancroid has declined in the United States (CDC, 2013), but chancroid is still endemic in other parts of the world such as Africa, Asia, Latin America, and parts of the Caribbean; a genital ulcer in a person with a history of travel to these areas should raise suspicion for chancroid (Lewis and Ison, 2006). Chancroid, like genital herpes and syphilis, is a risk factor for transmission of HIV (Magro et al, 1996).

A definitive diagnosis of chancroid requires culture on media not routinely available (Lockett et al, 1991). There are no FDA-approved tests. The CDC suggests that a probable diagnosis of chancroid can be made if (1) the patient has one or more painful ulcers;

(2) no evidence of *T. pallidum* is present on darkfield examination of ulcers or by serologic testing for syphilis performed at least 7 days after onset of the ulcers; (3) ulcers and lymphadenopathy, if present, are typical for chancroid; and (4) results of tests for HSV on the ulcer exudate are negative (CDC, 2010c). Treatment is with azithromycin 1 g in a single dose or ceftriaxone 250 mg IM in single dose or ciprofloxacin 500 mg orally twice per day for 3 days or erythromycin base 500 mg orally three times per day for 7 days. Patients should be tested for HIV at the time of diagnosis of chancroid. If initial test results were negative, repeat testing at 3 months for syphilis and HIV should be performed. Patients with HIV are less likely to respond to treatment, have slower healing of ulcers, and may require longer courses of therapy (CDC, 2010c).

Granuloma Inguinale

Granuloma inguinale is an infection by the intracellular gram-negative bacterium *Klebsiella granulomatis* (formerly called *Calymmatobacterium granulomatis*) that produces genital ulcers. Granuloma inguinale does not usually occur in the United States. The most common locations in the world for granuloma inguinale are Papua New Guinea, South Africa, parts of India and Brazil, and the aboriginal community in Australia (Lagergard et al, 2011). The incubation period averages 50 days (O'Farrell, 2002). The disease manifests as painless, slowly progressive ulcers on the genitals and perineum. Despite the name, inguinal involvement is uncommon (10%) (Velho et al, 2008). The lesions are described as beefy red because of high vascularity, and they bleed easily. The most common site of extragenital spread is the mouth, producing loss of teeth from bone destruction, but it can also occur in the pelvis, intra-abdominal organs, and other bones (especially the tibia) (Velho et al, 2008).

The bacterium is a strict human pathogen, which makes culture difficult. Diagnosis requires visualization of dark-staining Donovan bodies on crush preparation or biopsy, described by Donovan in 1905 (Richens, 2006). These are intracellular inclusions of the bacteria within the cytoplasm of macrophages and appear deep purple when stained with Wright, Giemsa, or Leishman stain (Lagergard et al, 2011). There are no FDA-cleared molecular tests for detection of *K. granulomatis*. Treatment is with doxycycline 100 mg orally twice per day for at least 3 weeks and until all lesions have healed (CDC, 2010c).

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is an infection by *Chlamydia*, specifically serovars L1, L2 or L3 (Mabey and Peeling, 2002). Traditionally, LGV is rare in developed countries but is endemic in parts of Africa, Asia, South America and the Caribbean (Mabey and Peeling, 2002). However, the incidence of LGV, especially in MSM, has been rising since the infection was first described in Western Europe in 2003, and LGV is occurring worldwide including in the United States (White, 2009). The incubation period is 3 to 30 days. A self-limited genital ulcer or papule sometimes is present at the site of infection but usually has disappeared by the time of presentation. The secondary stage is the most common presentation in heterosexuals and is marked by tender inguinal and/or femoral lymphadenopathy, typically unilateral (Fig. 15-7). Inguinal lymph nodes are more common in men because the lymph drainage of the cervix and vagina are to the retroperitoneal rather than the inguinal lymph nodes (Mabey and Peeling, 2002). Inguinal lymph nodes above and below the inguinal ligament can give rise to the "groove sign" in 10% to 20% of patients (Schachter and Osoba, 1983). Rectal exposure in women or MSM can result in proctitis with hemorrhoids, rectal or anal pain, rectal discharge, constipation, and fever (Arnold et al, 2013). A third stage can develop. If left untreated, LGV proctocolitis can develop into chronic colorectal fistulas and strictures. Chronic infection can also lead to lymphatic obstruction with elephantiasis of the genitalia in either sex. LGV does not appear to occur more frequently or with any more virulence in HIV-positive individuals (Jebbari et al, 2007).

Figure 15-7. Lymphogranuloma venereum with inguinal adenopathy.

Diagnosis is made by swab of lesions or aspiration of buboes from genitals or lymph nodes, sent for culture, direct immunofluorescence, or nucleic acid detection. NAATs are used for urethral specimens but are not FDA approved for rectal specimens. *Chlamydia* serology with complement fixation titers exceeding 1:64 can support the diagnosis of LGV (CDC, 2010c). When specific diagnostic testing is not available, the patient should be presumptively treated for LGV. Treatment is with doxycycline 100 mg orally twice per day for 21 days (CDC, 2010c).

Human Papillomavirus

Human papillomavirus (HPV) is a double-stranded DNA virus belonging to the Papillomaviridae family. More than 100 types of HPV exist, of which more than 40 types of HPV can infect the genital area and be sexually transmitted (Dunne et al, 2011). Types 6 and 11 are nononcogenic and are responsible for about 90% of anogenital warts (Gissmann et al, 1983; Garland et al, 2009). Other subtypes including 16 and 18 account for cervical cancer and other types of anogenital cancer including vulvar, vaginal, anal, and penile cancers (De Vuyst et al, 2009; Li et al, 2011). Although certain HPV types are associated with certain morphologic characteristics, the association is not absolute. The usual keratinizing squamous cell penile cancer is associated with HPV in only 11% of patients, with much higher rates of HPV DNA positivity strongly associated with either basaloid or warty changes (47%) or purely basaloid changes (75%) (Giuliano et al, 2008).

More than 50% of sexually active persons will become infected at least once in their lifetime (Myers et al, 2000). Approximately 70% of HPV infections resolve spontaneously in 1 year and 90% in 2 years, and HPV persistence develops in the remaining persons (Veldhuijzen et al, 2010). Transmission can occur from asymptomatic and subclinical patients. Among asymptomatic women in the general population, the prevalence of HPV infection ranges from 2% to 44%, and among men from 2.3% to 34.8% (Burchell et al, 2006). HPV infection starts at the basal cell layer of stratified squamous epithelial cells, which then stimulates cell proliferation in the epithelium. HPV warts can also occur in the urethra and can cause hematuria, dysuria, or difficulty voiding. Bowenoid papulosis involves reddish brown verrucous papules on the penis that are a low-grade carcinoma in situ with a chance of malignant transformation of 2% to 3% (Cubie, 2013). Buschke-Lowenstein tumors, or giant condyloma acuminatum, are large verrucous exophytic lesions on the penis or perineum, associated with HPV-6 or HPV-11. These tumors are considered a low-grade verrucous carcinoma, and in general only local invasion is present (Armstrong et al, 2009; Cubie, 2013).

Lesions such as warts can be seen clinically (Figs. 15-8 and 15-9), but HPV virus can also be present and subclinical. Latent viruses are detectable only through demonstration of HPV DNA in skin or

Figure 15-8. Meatal wart caused by human papillomavirus.

Figure 15-9. Penile warts.

mucosa (Cubie, 2013). The use of acetic acid to detect nonvisible skin lesions is not recommended because of the large number of false-positive results. HPV tests that detect viral nucleic acid (i.e., DNA or RNA) or capsid protein are available for women older than 30 years undergoing cervical cancer screening. These tests should not be used for men, for women younger than 20 years, or as a general test for STDs (CDC, 2010c). In the following situations, biopsy may be warranted to rule out a malignant lesion: (1) the diagnosis is uncertain; (2) the patient is immunocompromised; (3) the warts are pigmented, indurated, or fixed; (4) the lesions do not respond to or they worsen with standard treatment; (5) there is persistent ulceration or bleeding.

Treatment

The goal of treatment is removal of the warts; treatment will not eradicate the infection. Treatment is guided by wart size, number, and location, and patient preference. Treatment regimens are divided into patient-applied and provider-applied modalities (CDC, 2010c).

Patient-applied treatments for HPV (note: these are not approved for use during pregnancy):

1. Podofilox 0.5% solution or gel up to 0.5 mL/day, applied twice per day for 3 days, then no therapy for 4 days, up to four cycles. Total wart area should not exceed 10 cm².
2. Imiquimod cream 5% once daily at bedtime, three times per week up to 16 weeks; should be washed off 6 to 10 hours after application.
3. Sinecatechins 15% ointment (sinecatechins are major polyphenols found in green tea leaves) (Dunne et al, 2011), three times per day for up to 16 weeks. This should not be washed off after application. Avoid sexual contact with the ointment on the skin. Not recommended in patients with HIV, those

who are otherwise immunocompromised, or those with herpes.

Provider-administered treatments:

4. Podophyllin resin 10% to 25% in tincture of benzoin, applied to wart and allowed to dry. This can be repeated weekly. To avoid complications from systemic absorption and toxicity, ensure that (1) application is limited to an area less than 10 cm² or less than 0.5 mL of podophyllin is used and (2) the treatment area does not contain any open lesions or wounds.
5. Cryotherapy such as liquid nitrogen, which induces cytolysis. Application can be repeated every 1 to 2 weeks. Providers should be trained in the use of this method. Large warts may need local anesthesia because of possible pain with application.
6. Trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80% to 90%; these acids destroy warts by chemical coagulation of wart proteins. Apply to wart and allow to dry before patient stands up; if intense pain ensues after administration, neutralize the acid with soap and water or sodium bicarbonate. Can be repeated weekly.
7. Surgical therapy including direct excision with scissors, tangential shave excision, curettage, or laser therapy using a CO₂ laser (Aynaud et al, 2008). Consider collaboration with a plastic surgeon for large lesions that require large areas of excision, especially on the penis or in the groin creases.

Urethral warts are usually caused by HPV subtypes at low risk for malignancy (Beutner et al, 1999). Treatments for urethral meatal warts include cryotherapy with liquid nitrogen and podophyllin 10% to 25% compounded in tincture of benzoin. The adjacent skin must be dry before treatment. Men with external urethral warts should undergo urethroscopy to rule out intraurethral warts (Fralick et al, 1994). Bladder warts may also be present. 5-Fluorouracil has been used intraurethrally, but its use is limited by the significant inflammation produced. Holmium laser can be used for lesions in the urethra and bladder. A biopsy is recommended to rule out any malignant or precancerous lesions.

Human Papillomavirus Vaccine

In June 2006, a quadrivalent HPV vaccine (Gardasil) was licensed for use in the United States in girls and women aged 9 to 26 years (Markowitz et al, 2007). In October 2009, this vaccine also was licensed for use in boys and men aged 9 to 26 years (CDC, 2010b). This vaccine provides protection against HPV types 6, 11, 16, and 18. In October 2009, a bivalent HPV vaccine (Cervarix) that provides protection against types 16 and 18 was licensed for use in girls and women aged 10 to 25 years (CDC, 2010a). Overall the bivalent vaccine prevents HPV types that cause 70% of cervical cancer and the quadrivalent vaccine prevents HPV types that cause 70% of cervical cancers and 90% of genital warts. Either vaccine is recommended for girls starting at age 11 to 12 and can be given to girls as young as age 9. Girls and women aged 13 to 26 who have not started or completed the vaccine series should also receive the vaccine. It is most effective if started before the onset of sexual activity. The vaccine is given as a three-dose series of intramuscular shots over a 6-month period. Women should still undergo regular cervical cancer screening because 30% of cervical cancer is caused by other HPV subtypes. The vaccines are not licensed for use in women older than 26 years in the United States (Dunne et al, 2011).

The quadrivalent vaccine is used in males to prevent genital warts and in both genders to prevent anal cancer (Dunne et al, 2011). MSM are particularly at risk for developing anal intraepithelial neoplasia and anal cancer (Burchell et al, 2006). As in women and girls, it is best started before the onset of sexual activity. The vaccines are designed to prevent infection and are not effective in clearing an infection once established (Markowitz, 2007). The use of the vaccine is still relatively low, with 49% of girls and women aged 13 to 19 having received at least one dose and 32% having received three doses in a 2010 survey. Despite

Figure 15-10. Scabies affecting the penis.

Figure 15-11. Molluscum contagiosum on the abdomen.

low rates of use, the prevalence of vaccine HPV subtypes in girls and women declined from 11.5% during the years 2003-2006 to 5.1% during the period 2007-2010 after initiation of the vaccine (Markowitz et al, 2013).

Scabies

Scabies is a skin infection caused by the mite *Sarcoptes scabiei* var. *hominis* and has been known for over 2500 years (Chosidow, 2000). The female lays eggs in the skin, and transmission is by person-to-person skin-to-skin contact with passage of pregnant female mites. This can occur during sexual contact (Fig. 15-10). Scabies also commonly passes from person to person in crowded conditions (Hay et al, 2013) and by contact with infected bedding or clothing. Symptoms usually do not appear for 2 to 6 weeks after infestation, and infected persons can pass the mites in the absence of symptoms (Chosidow, 2000). The most common symptoms are skin rash and itching, especially at night, from an allergic reaction to the mite proteins. Female scabies mites can tunnel under the skin, producing tiny raised and crooked or serpiginous lines on the skin. Scratching at a sore can lead to infection with *Staphylococcus aureus* or β -hemolytic streptococci. These secondary infections have been associated with poststreptococcal glomerulonephritis (Svartman et al, 1972).

A more concentrated area of mites can form a crust and is called *crusted* or *Norwegian scabies*. This may occur in persons who have difficulty scratching or are prevented from scratching, such as those with spinal cord injury or mental disability, and also occurs in elderly and immunocompromised persons, including those with HIV infection. These individuals are very contagious (Chosidow, 2000). Diagnosis is made by demonstration of mites, mite eggs, or fecal matter (scybala) on microscopic examination of a skin scraping. Treatment is with permethrin cream (5%) applied to all areas of the body from the neck down and washed off after 8 to 14 hours or ivermectin 200 μ g/kg orally, repeated in 2 weeks. An alternative is lindane (1%) lotion or cream, but this is used only if the patient cannot tolerate other therapies or if other therapies have failed, because lindane toxicity causes central nervous system (CNS) effects, seizures, and aplastic anemia (Chosidow, 2006). Bedding and clothing should be decontaminated by washing and drying on the hot cycles, or by removal and placement in a decontamination bag for longer than 72 hours. Scabies do not generally survive more than 2 or 3 days away from human skin.

Pediculosis Pubis (*Phthirus pubis*): Pubic or Crab Louse

Pediculosis (lice) has been known for 10,000 years (Orion et al, 2004). Lice are obligate bloodsucking parasites of humans. The pubic lice are much shorter than those that occur on the scalp or body. Transmission requires close contact. The female's life cycle

lasts for 1 to 3 months. Females lay eggs (nits) at the skin-hair junction; they mature into lice in 20 days. Pubic lice infestation is common in sexually active persons and tends to recur in gay men. Transmission is not prevented with use of condoms. Pubic lice specifically have a serrated surface on their claws to facilitate clinging to flat, hairless surfaces (Orion et al, 2006). In children, the presence of pubic lice does not imply a definite sexual contact, as they can be acquired by contact with an infected parent (Chosidow, 2000).

The typical presentation is pruritus, which is caused by a delayed hypersensitivity reaction to the lice. First exposure can result in symptoms in 2 to 6 weeks (Orion et al, 2004). Symptoms develop more quickly with subsequent exposures, on the order of 1 to 2 days. Eggs remain in situ after releasing their larvae (nymphs), and empty shells can remain on the hair for many months after the infection has been eradicated; therefore the diagnosis is only by identifying live lice or viable eggs (Chosidow, 2000). Treatment is permethrin 1% cream rinse applied to affected areas and washed off after 10 minutes or pyrethrins with piperonyl butoxide applied to affected areas and washed off after 10 minutes (CDC, 2010c). Bedding and clothing should be decontaminated by dry cleaning; washing and drying at high temperature; or removal from body contact for 72 hours. Patients with pediculosis pubis should be evaluated for other STDs.

Molluscum Contagiosum

Molluscum contagiosum is a superficial skin disease caused by the pox virus. The virus contains double-stranded DNA and replicates entirely in the cytoplasm of infected cells, independent of the host nucleus (Myskowski, 1997). It can be sexually transmitted. Characteristic lesions are small, discrete waxy papules 3 to 5 mm in diameter, with a central depression (Fig. 15-11). The central core can be expressed, producing a white material. Localized eczematous dermatitis is commonly seen around the lesions (Chen et al, 2013). The infection is usually self-limited and spontaneously disappears in 6 to 12 months, but may take up to 4 years to resolve. However, infection in immunocompromised individuals, such as those with HIV, is typically more severe and extensive. Patients with HIV may develop widespread and large lesions including "giant" lesions larger than 15 mm in diameter (Cronin et al, 1996). Increase in the number of lesions can be seen in HIV patients as a manifestation of the immune reconstitution syndrome, which occurs shortly after the initiation of antiretroviral therapy (ART) in severely immunocompromised patients (Pereira et al, 2007). Diagnosis is generally on the basis of the characteristic appearance of skin lesions. Biopsy is indicated in cases of unclear diagnosis, especially in immunocompromised patients with unusual presentations in which malignancy must be excluded (Trobe and Lenzi, 2005). Skin biopsy will show typical "molluscum bodies" or Henderson-Patterson bodies,

which are eosinophilic inclusions in the epidermis (Eleftheriou et al, 2011).

One option for treatment is waiting, because the infection is generally self-limited. Rapid treatment options include cryotherapy (freezing the lesions), curettage with piercing of the lesion and removal of the contents, and laser therapy. Oral therapy with cimetidine has been used (Dohil and Prendiville, 1996). Topical therapies include podophyllotoxin cream 0.5% in men (this cannot be used in pregnant women because of fetal toxicity), iodine and salicylic acid, potassium hydroxide (KOH), cantharidin (a blistering agent), and imiquimod (Gottlieb and Myskowski, 1994). A first treatment in HIV patients is to use ART. The number of molluscum contagiosum lesions is inversely proportional to the CD4 cell count (Myskowski, 1997). Regression of recalcitrant molluscum contagiosum lesions after initiation of ART has been reported (Cattelan et al, 1999). Systemic and topical cidofovir may be beneficial in treating large molluscum contagiosum lesions associated with immunosuppression (Davies et al, 1999).

Vaginitis

Vaginal infections are characterized by discharge, itching, or odor. Three diseases most frequently associated with vaginal discharge are bacterial vaginosis (BV), trichomoniasis, and candidiasis. BV and trichomoniasis are sexually transmitted. The diagnosis can be made via Amsel's criteria: pH, a KOH test, and microscopic examination of fresh samples of the discharge (Table 15-6).

Bacterial Vaginosis

Bacterial vaginosis is caused by replacement of the normal hydrogen peroxide-producing *Lactobacillus* species in the vagina with high concentrations of anaerobic bacteria including *Prevotella*, *Mobiluncus*, *Gardnerella vaginalis*, *Ureaplasma*, *Mycoplasma*, and other fastidious anaerobes. Although BV is the most common diagnosis in women seeking care for vaginal symptoms, most women with BV are asymptomatic. Women with BV are at risk for acquisition of some STDs including HIV, *N. gonorrhoeae*, *C. trachomatis*, and HSV-2. Diagnosis can be made by Gram stain, evaluating for relative amounts of *Lactobacillus* and other bacteria characteristic of BV. Characteristic findings for BV on microscopic examination are clue cells, which are vaginal epithelial cells covered with bacteria. Recommended treatment regimens include metronidazole 500 mg orally twice per day for 7 days or metronidazole 0.75%, one full applicator (5 g) intravaginally once per day for 5 days or clindamycin cream 2%, one full applicator (5 g) intravaginally at bedtime for 7 days (CDC, 2010c). Note that clindamycin is oil based and may weaken condoms and diaphragms for 5 days after use.

Trichomoniasis

Trichomoniasis is caused by the protozoan *T. vaginalis*. The discharge from trichomoniasis is diffuse, malodorous, and yellow

green with vulvar irritation; however, not all women infected are symptomatic. Diagnosis is usually by microscopy of vaginal secretions showing the *Trichomonas* organisms. The sensitivity of microscopy is only 60% to 70%. There are two FDA-approved rapid tests for *Trichomonas*: the OSOM Trichomonas Rapid Test (Sekisui Diagnostics, Lexington, MA), which uses immunochromatographic capillary flow dipstick technology, and the Affirm VPIII (Becton, Dickinson and Company, Sparks, MD), which is a nucleic acid probe test. Culture is also available for *T. vaginalis*. Treatment is metronidazole 2 g orally in a single dose or tinidazole 2 g orally in single dose (CDC, 2010c). **Patients are advised to abstain from alcohol consumption for 24 hours after taking metronidazole and 72 hours after tinidazole.** Evidence suggests interaction between HIV and *T. vaginalis* such that *T. vaginalis* infection in HIV-infected women might enhance HIV transmission by increasing genital shedding of the virus (Wang et al, 2001). In women with HIV, a multidose treatment regimen of metronidazole, 500 mg orally given twice per day for 7 days, is recommended instead of one 2-g dose (Kissinger et al, 2008; Kissinger et al, 2010).

Candidiasis

Vulvovaginal candidiasis is usually caused by *Candida albicans* but occasionally by other species of *Candida* or yeasts. Vaginal candidiasis is classified as complicated or uncomplicated based on clinical criteria (CDC, 2010c). Uncomplicated cases involve infections that are sporadic or infrequent, produce mild to moderate symptoms, are likely to be caused by *C. albicans*, and occur in immunocompetent women. Complicated cases involve recurrent candidiasis (four or more episodes of symptomatic vulvovaginal candidiasis in 1 year), severe infection, non-*C. albicans* cause, and women with uncontrolled diabetes, debilitation, or immunocompromise. Approximately 10% to 20% of cases of vulvovaginal candidiasis will be complicated. Vaginal cultures should be obtained in patients with recurrent vulvovaginal candidiasis because conventional antimycotic treatments are not as effective against atypical species such as *Candida glabrata*. The diagnosis is made via wet prep with saline or KOH; a Gram stain of vaginal discharge that demonstrates yeast, hyphae, or pseudohyphae; or a culture that shows *Candida* or other yeast species. Wet mounts should first be done for all patients, and culture used for those with symptoms with negative wet mounts.

Treatment for uncomplicated vulvovaginal candidiasis includes numerous over-the-counter intravaginal agents including butoconazole or clotrimazole creams, miconazole as a cream or intravaginal suppository, or tioconazole ointment. Prescription treatment formulations include butoconazole cream, terconazole cream or vaginal suppository, nystatin vaginal suppository, or one oral dose of fluconazole 150 mg (CDC, 2010c). A woman who has persistent symptoms or a recurrence 2 months after having used an over-the-counter treatment should be evaluated. In cases of recurrence, a longer duration of therapy such as 7 to 14 days of topical therapy or a dose of fluconazole every third day for a total of three doses is

TABLE 15-6 Differential Diagnosis of Vaginitis in Women

	VAGINAL DISCHARGE	pH	WHITE BLOOD CELLS	MICROSCOPY	SYMPTOMS
Normal	White, thick, smooth	≤4.5	Absent	Lactobacilli	None
Candidiasis	White, thick, curdlike	≤4.5	Absent	Mycelia	Vulvar pruritus, external or superficial dysuria
Trichomoniasis	Frothy or purulent	≥4.5	Present	Mobile trichomonads present Amine odor	Vulvar erythema and edema, punctate strawberry lesions on cervix
Bacterial vaginosis	Thin, white homogeneous	≥4.5	Absent	Paucity of lactobacilli (75% of patients) Amine odor Clue cells	Fishy odor and increased vaginal discharge

recommended (CDC, 2010c). Treatment for non-*C. albicans* vulvo-vaginal candidiasis is not standardized.

HUMAN IMMUNODEFICIENCY VIRUS/ACQUIRED IMMUNODEFICIENCY SYNDROME AND THE UROLOGIST

HIV is a retrovirus that infects T cells and dendritic cells (Klasse, 2012). HIV spreads through blood, semen, vaginal fluid, or breast milk. The resultant immunosuppression leads to AIDS. The diagnosis of AIDS is made if the CD4 count is less than 200 cells/mm³ or if there is a serious opportunistic infection, neoplasm, or other life-threatening condition. A total of 26 conditions are AIDS defining, including cervical cancer, lymphomas, and infections with *Candida* and CMV (National Institutes of Health, 2013).

Estimates of the national HIV incidence in the United States are calculated by the CDC. At the end of 2010, approximately 1.1 million Americans were living with HIV, and it was estimated that 16% did not know they were infected (Lansky et al, 2010). Approximately 50,000 new infections occur each year, a number that has remained stable since the mid-1990s (Hall et al, 2008). HIV occurs more often in some populations. Of new infections, two thirds occur in MSM, with over half occurring in young black men. Heterosexuals accounted for one quarter of all new infections in 2010, two thirds of those being women. Injections drug users made up 8% to 10% of new cases (Lansky et al, 2010). The most affected age group was 25 to 34 years (31%), followed by 13 to 24 years (26%) and 35 to 44 years (24%) (CDC, 2014).

See Expert Consult website for details.

Diagnosis of Human Immunodeficiency Virus Infection

The CDC recommends HIV screening for all patients aged 13 to 64 in health care settings (Branson et al, 2006). Patients should be counseled and notified that testing will be performed and given the option to decline or defer testing. Written consent is not usually required. Diagnosis of HIV includes using serologic tests that detect antibodies against HIV-1 (and HIV-2) and virologic tests that detect HIV antigens or RNA. The initial test is a screening test for antibodies, the conventional or rapid enzyme immunoassay (EIA). The initial result can be obtained in 30 minutes. Positive or reactive screening tests must be confirmed by a supplemental antibody test, Western blot and indirect immunofluorescence assay (IFA), or virologic test, the HIV-1 RNA assay (CDC, 2004). A positive confirmation test result establishes the diagnosis. HIV is detectable in 95% of patients within 3 months after infection. During this initial 3-month period, the “window” period, the screening test

result may be negative but the person may still be infected. Virologic tests for HIV-1 RNA can be used to detect an acute infection in persons negative for HIV antibodies. This should be used with the initial antibody test in the setting of suspicion of acute retroviral syndrome (see the discussion of acute infection). A positive RNA test result should be confirmed by a subsequent antibody test. The majority of infections in the United States are HIV-1. HIV-2 infection should be suspected in persons with an unusual clinical presentation or with risk factors including having lived or having a sex partner from an endemic area (West Africa, Portugal), having a sex partner known to be HIV-2 positive, or having had a blood transfusion or nonsterile injection in an endemic area (CDC, 2004, 2010c).

See Expert Consult website for details.

Urologic Manifestations of Human Immunodeficiency Virus Infection

Interaction with other Sexually Transmitted Diseases

Testing for HIV is recommended in anyone with a diagnosed STD or who is at risk for an STD (CDC, 2010c). In many populations, the pattern of HIV acquisition parallels that of other STDs (Quinn et al, 1988; Clotney and Dallabetta, 1993); the presence of an STD increases the risk for both transmitting and acquiring HIV infection. STDs that produce ulcers are particularly associated with HIV; the adjusted OR for the effect of genital ulcer disease on increase in the risk of acquiring HIV is 2.2 to 11.3 (Quinn et al, 1990; Hook et al, 1992; Fleming and Wasserheit, 1999).

Several factors likely contribute to this association (Fleming and Wasserheit, 1999). Genital ulcers bleed frequently during intercourse, potentially leading to increased infectiousness. HIV has been detected in genital ulcer exudates (Kreiss et al, 1989). In HIV-seronegative individuals, ulcers may increase susceptibility to infection by disrupting mucosal integrity and by recruiting HIV-susceptible immune cells to the site of the ulcer, as in *H. ducreyi* infection (Magro et al, 1996). HSV infection may make keratinocytes also vulnerable to HIV, expanding the targets for infection (Heng et al, 1994). HSV also increases HIV replication in persons infected with both viruses (Van de Perre et al, 2008). Non-ulcer-producing STDs such as chlamydia and gonorrhea increase HIV shedding by recruiting HIV inflammatory cells in infected individuals (Moss et al, 1995). HIV shedding is associated with gonorrhea, cervicitis, and vaginitis in women (Mostad et al, 1997); higher levels are associated with concomitant infection with *M. genitalium* (Manhart et al, 2008). HIV-infected patients can also have larger lesions as in the case of HPV with giant condyloma (Fig. 15-16).

Figure 15-16. A and B, Acquired immunodeficiency syndrome patient with extensive genital condyloma.

Human Immunodeficiency Virus Virology

There are two types of HIV virus: HIV-1 and HIV-2. There are very few cases of HIV-2 infection in the developed world. HIV-2 is less virulent and is transmitted less readily (Campbell-Yesufu and Gandhi, 2011). Therefore this chapter deals exclusively with HIV-1. HIV is a retrovirus, in the family *Lentivirus* (Emerman and Malim, 1998). The genetic material in HIV is single-strand RNA. After entry into the targeted cell, the RNA is reverse transcribed by a reverse transcriptase into a double-stranded DNA. This new DNA is assembled into complexes, which then associate with the target cell chromatin and integrate via the action of viral integrase (Cavazza et al, 2013). The cell then translates and transcribes the viral genes to produce proteins that will assemble new copies of the virus. Copies of the virus are called *virions*.

Structure of the Human Immunodeficiency Virus

(Figs. 15-12 and 15-13)

Viral Envelope

The virus is shaped like a sphere. It is covered by an outer envelope, a lipid bilayer derived from the host cell when it buds out of the cell. Embedded in the envelope is a complex of proteins known as "Env." There is initially a precursor glycoprotein 160 (gp160) which is cleaved by a protease in the trans-Golgi network. It is cleaved into an outer subunit gp120 and a transmembrane subunit gp41. After proteolysis, the gp120 and gp41 remain coupled as noncovalent heterodimers (Klasse, 2012). These proteins protrude through the surface. The cap is made of three molecules of gp120, and the stem is three molecules of gp41. HIV must fuse its phospholipid bilayer surrounding the virus with a host membrane to be able to deliver the viral core (Grove and Marsh, 2011). The entry by fusion is mediated by the envelope glycoprotein (Env).

Viral Core

Within the envelope is a core or capsid, shaped like a cone, made of viral protein p24. Within the capsid are two copies of single-stranded RNA. Each RNA strand has a complete copy of the viral genes. Several structural genes are worth noting: *gag*, *pol*, and *env*. The *env* codes for a precursor protein gp160, which is then broken down to gp120 and gp41. There are regulatory genes including *tat*, *rev*, *nef*, *vif*, *vpr*, and *vpu* that are involved with replication, virulence, and spread of disease (Emerman and Malim, 1998). Three core enzymes involved in later replication are reverse transcriptase, integrase, and protease.

Viral RNA

The ends of each strand of RNA contain a sequence called the *long terminal repeat* (LTR). Parts of the LTR function as switches to control production of new viruses. They are triggered by proteins from either HIV or the host cell.

Virus Entry and Replication (Fig. 15-14)

The virus enters a cell itself by endocytosis, with different forms of endocytosis depending on the cell type (Miyauchi et al, 2009). The HIV virion can infect a cell only if it has the necessary receptor. Glycoprotein gp120 has a high affinity binding site for the T-lymphocyte receptor CD4 (Sattentau et al, 1986; Sattentau and Weiss, 1988). Binding of gp120 to CD4 triggers conformational changes in Env that enable interactions with a coreceptor, a member of the chemokine family, usually CCR5 or CXCR4 (Alkhatib et al, 1996). This interaction in turn produces more changes in Env, releasing the fusogenic potential of gp41 (Platt et al, 2007). The native structure of gp41 is unknown, but its function is described. The N terminal 20 residues are called the *fusion peptide*. Fusion is dependent on areas called the *membrane proximal external region* (MPER) and the *transmembrane domain* (Pejchal and Wilson, 2010).

Figure 15-12. Human immunodeficiency virus (HIV) virion. HIV has a spheric shape, an outer envelope, variable surface projections, and an icosahedral capsid containing ribonucleoprotein complexed with a core shell. (Courtesy Centers for Disease Control and Prevention.)

The long cytoplasmic tail also modulates the confirmation of external Env and its ability to fuse (Bhakta et al, 2011). The cytoplasmic tail is next to the matrix protein, which forms a shell underneath the envelope after cleavage of the Gag precursor. Virions become fusion competent as they mature only by cleaving and rearranging the Gag. The tail also plays a role in fusion by Gag, and also in the noncovalent association of gp120 with gp41 (Davis et al, 2006).

Other cell surface molecules aid the attachment of the virus to specific cell surface receptors (Geijtenbeek et al, 2000a; Geijtenbeek et al, 2000b): (1) Heparin sulfate moieties interact with positively charged side chains of Env. (2) DC-SIGN and other lectins on dendritic cells anchor the virus via glycans on Env. (3) ICAM-1 on the virion binds to LFA-1 receptor on lymphocytes. Following fusion, the virion is uncoated by a virion encoded protease. Once in the cell, viral DNA is made by reverse transcriptase. This occurs within 4-6 hours of infection. The final product is double stranded viral DNA. It is then transported across the nucleus and integrates into the host DNA by viral integrase.

Virus Packaging and Assembly

New viral RNA and proteins are made by the host cell. Viral gene expression and replication are upregulated by the virion-encoded proteins Tat and Rev. The RNA and proteins are moved to the cell surface and form a new immature HIV form (National Institutes of Allergy and Infectious Diseases, 2014). Maturation occurs by a protease releasing individual HIV proteins. They are incorporated when

Figure 15-13. Human immunodeficiency virus virion. (Courtesy National Institute of Allergy and Infectious Diseases.)

virus particles, or virions, assemble and bud from the infected cell in a process driven by the viral Gag protein (Klasse, 2012).

Viral Synapse and Cell-to-Cell Transmission

An HIV-infected cell can establish contact with a target cell and transmit HIV infection across what is called a *virologic synapse*. This involves viral budding and Env-mediated virion fusion. It is not clear if mucosal infection is by virions (virus itself) or cell-to-cell transmission including T cells. During virologic synapse infection, virions accumulate within target cell endosomes. After transfer, the virion undergoes proteolytic maturation within the acceptor cell endosomes, and viral membrane fusion. Fusion with the other cell must await Gag cleavage; inhibitors of the viral protease block fusion after internalization (Dale et al, 2011). Particle maturation activates viral fusion in target T cells. Viral fusion can occur in compartments away from the synapse and may be a way for HIV to avoid antibody detection and neutralization (Dale et al, 2011).

Virus Heterogeneity and Mechanisms to Escape Therapy

Env has multiple defenses against neutralizing antibodies. Half of gp120 consists of high mannose glycans forming a dense shield (Klasse, 2012). It has hypervariable regions, V1, V2, and V3, with amino acid changes that affect glycosylation sites and produce escape from neutralization (Pejchal and Wilson, 2010). The three-dimensional structure also secludes the receptor binding sites from antibody binding (Klasse, 2012). Env has an unusual conformational flexibility (Pejchal and Wilson, 2010), and unliganded trimers are not conformationally identical (Liu et al, 2008). Binding different sites and ligands also produces variation in the quaternary structure of Env gp120 peptides (Tran et al, 2012). There is a high error rate of the reverse transcriptase resulting in diversity in the Env even in one cell infected by one virion. Variations in CD4 are less common. Common is variation in the coreceptors CCR5 or CXCR5, which has four tyrosine residues at its N terminus

extracellular region, that can be sulfated with various permutations with different effects on entry (Seibert et al, 2002). CXCR4 is also sulfated (Seibert et al, 2008).

Pathogenesis and Natural History of Human Immunodeficiency Virus Infection

Primary Infection

The initial infection with HIV resembles other infections such as mononucleosis or a nonspecific acute viral illness. The initial syndrome lasts approximately 14 days and occurs in 40% to 90% of patients, with variable severity. Common symptoms include fever, sore throat, fatigue, weight loss, and myalgia (Schacker et al, 1996). A maculopapular rash, usually occurring on the trunk, that is composed of CD4+ cells and local vasculitis is suggestive of acute HIV infection. The initial illness is associated with high plasma levels of the virus, often more than 1 million HIV RNA copies per milliliter, a decrease in CD4+ T-cell count, and a large increase in CD8+ T-cell count. The increase in CD8+ cells is the cellular immune attempt to limit virus replication and contain the infection (Musey et al, 1997). Neutralizing antibodies are not usually detectable until weeks to months after initial infection (Safrit and Koup, 1995). A marked decrease in plasma virus levels corresponds to resolution of the clinical symptoms. After the initial infection, the remaining viral load is prognostic of progression; those with the highest viral load or set point have the greatest risk of progression (Mellors et al, 1996; Kahn and Walker, 1998).

Chronic Asymptomatic Infection

After primary HIV infection, there can be a long phase of clinical latency, usually lasting around 10 years. Although viral and blood levels are relatively stable during this period, there is viral replication in the dendritic cell network in lymphoid tissue. Approximately 98% of the total T cells in the body are found in the

Figure 15-14. Viral replication cycle. HIV, human immunodeficiency virus. (Courtesy National Institute of Allergy and Infectious Diseases.)

secondary lymphoid organs and tissues including lymph nodes, spleen, and mucosal-associated lymphoid tissue such as gut-associated lymphoid tissue (GALT) and bronchial-associated lymphoid tissue (BALT) (Schacker, 2008). Despite relatively stable blood levels of virus, there is replication in this lymph tissue, leading to immunosuppression and progression of disease (Pantaleo et al, 1998). Eventually immunosuppression leads to increased viral loads, a drop in CD4⁺ cell counts, and conversion to AIDS.

Variation in Clinical Course

Several different clinical courses are observed in untreated patients with HIV infection (Sheppard et al, 1991, 1993; Haynes et al, 1996):

1. Typical progression (60% to 70%): Median time of development of AIDS is 10 to 11 years in the absence of treatment.

2. Rapid progression (10% to 20%): development of AIDS in less than 5 years. These patients have a persistently high viral load, rapid decline in CD4+ T cells within 2 to 3 years after infection, decreased levels of CD8+ cells, and lower levels of HIV antibodies (Janvier et al, 1993).
3. Slow progression (5% to 15%): This group remains free of AIDS for 10 to 15 years after infection, with stable CD4 counts. Genetic variation in the host may play a role in this lack of progression, including alleles for the coreceptors necessary for infection including CCR5 (Ioannidis et al, 2001).
4. Long-term nonprogressors (1%): no signs of disease progression after 8 to 10 years of infection. They generally have lower viral load and may be infected with a less virulent virus (Deacon et al, 1995).

Pathogenesis of Infection

The most common route of HIV transmission is sexual transmission at the genital mucosa (Royce et al, 1997). Dendritic cells, which are antigen presenting cells (Mellman and Steinman, 2001), are present in the vaginal epithelium (Spira et al, 1996). These cells can prime T cells. T cells that have not yet been exposed to antigen are called *naïve*. After presentation of antigen, these T cells are then programmed to respond to that particular antigen. Central memory T cells have limited effector function but can proliferate if reexposed to the antigen; the other class of memory T cells are effector memory T cells, which home to peripheral tissues and sites of inflammation to protect against pathogens (Schacker, 2008). Dendritic cells express specific chemokines that attract naïve T cells rather than memory T cells (Cameron et al, 1996). One is called "DC-SIGN," a specific membrane protein with an external mannose binding C-type lectin domain (Steinman, 2000). Dendritic cells subsequently migrate to lymph nodes, usually within 2 days, and then rapidly disseminate throughout the lymphoid tissue. Detectable virus in the blood is present 4 to 11 days after initial infection.

Overall there are variable rates of sexual transmission, and multiple factors including behavioral, biologic, genetic, and immunologic factors affect risk of transmission. A large review of this topic found several associations with risk of heterosexual transmission of HIV; the risk of transmission was greater for low-income countries, commercial sex exposure, presence of genitourinary ulcer disease, and higher viral load. Early- and late-stage HIV were associated with a greater risk of transmission than the asymptomatic

phase, on the order of 7 to 9 times increased risk (Boily et al, 2009).

Similar to findings in MSM, receptive anal intercourse had a higher rate of infection than vaginal sex (Boily et al, 2009). The risk of transmission during unprotected anal intercourse is greater than that of unprotected vaginal intercourse. Rectal mucosa lacks the protective humoral immune barrier found in secretions in the vagina and cervix (Belec et al, 1995) and is also more susceptible to traumatic abrasions that can break the epithelial barrier (Levy, 1993). The contribution of anal intercourse as well as increased risk with increased number of sex partners was recognized early in the study of HIV/AIDS (Winkelstein et al, 1987). The risk of transmission is not different for heterosexual male-to-female contact or for MSM (Baggaley et al, 2010). As a comparison, pooled samples of infectivity studies indicate per-act infectiveness for male-to-female vaginal intercourse of 0.08% (95% confidence interval [CI] 0.06 to 0.11) in developed countries and 0.30% (95% CI 0.14 to 0.063) in developing countries (Boily et al, 2009); for receptive anal intercourse of 1.4% (95% CI 0.2 to 2.5) (Baggaley et al, 2010); and for orogenital contact of 0.04% (95% CI 0.01 to 0.17) (Vittinghoff et al, 1999).

The Boily study (Boily et al, 2009) also confirmed findings of other studies that indicate a significant increase in infection in men who are uncircumcised. Overall the increase in transmission for uncircumcised status and genital ulcer disease was 3 to 8 times. This is somewhat higher than in three recent randomized controlled trials of circumcision (Auvert et al, 2005; Bailey et al, 2007; Gray et al, 2007). The efficacy rate of circumcision for reducing susceptibility to HIV transmission was 50% to 60% in these three clinical trials (Auvert et al, 2005; Bailey et al, 2007; Gray et al, 2007).

Several factors may facilitate heterosexual transmission by vaginal sex. Release of semen into the vagina triggers an influx of neutrophils to help remove excess spermatozoa; these neutrophils can be associated with a transient loss of epithelial barrier function (Southern, 2013). Semen also carries cytokines such as interleukin-8 (IL-8), which is chemoattractant for neutrophils, and also induces inflammation and immunologic changes in the cervix (Sharkey et al, 2012). Sexually active young women typically have mild to moderate cervicitis, and the ongoing inflammatory state is thought to be from repeated unprotected exposure to semen. Although hormonal contraceptives can change vaginal epithelium, their use does not appear to increase risk of HIV transmission (Heffron et al, 2013).

Treatment for Human Immunodeficiency Virus Infection

Because of persistence in reservoirs, treatment for HIV will not completely eradicate the virus. However, treatment will prevent or delay HIV-associated morbidity and mortality, because without treatment the vast majority of patients will develop progressive immunosuppression leading to AIDS and death. ART is used to inhibit the replication of HIV with the goal of keeping viral loads as measured by HIV RNA levels below the level detectable by commercial assays (National Institutes of Health, 2013). Measures of viral replication are predictive of disease progression, because time to clinical disease progression and mortality is fastest in those with the highest viral loads (Mellors et al, 1996). The concept of viremia copy-years as a measure of cumulative exposure to the virus is independently associated with mortality (Mugavero et al, 2011).

The benefit of treatment may depend on the starting CD4 count, but treatment guidelines recommend treatment for all patients regardless of CD4 count (U.S. Department of Health and Human Services Panel on Guidelines for Adults and Adolescents, 2013). In patients with CD4 counts below 200 cells/mm³ and/or a history of AIDS-defining illness, ART clearly improves survival and delays disease progression (Hammer et al, 1997; Zolopa et al, 2009). In patients with cell counts between 350 and 500 cells/mm³, starting ART reduces HIV-related disease progression, with an unclear effect on mortality (Kitahata et al, 2009; HIV-CAUSAL Collaboration et al, 2011). Some trials have not shown a benefit in starting ART in patients with CD4 cell counts above 500 cells/mm³ (When To Start Consortium et al, 2009), but other studies have shown that universal treatment of all increased the 1-year level of viral suppression in patients with a cell count above 500 cells/mm³ from 9% to 14% per year up to more than 52% (Geng et al, 2012).

ART may be beneficial even when started later in therapy. Reduction in viral levels can also prevent some of the known non-AIDS-defining complications, including renal disease, liver disease, cardiovascular disease, neurologic disease, and malignancies. HIV-associated nephropathy (HIVAN) specifically is discussed elsewhere; the risk of renal disease is on the order of threefold in persons with HIV (Islam et al, 2012b). HIV is associated with more rapid progression of viral hepatitis-related liver disease (Thein et al, 2008). Over time, HIV-infected individuals are at greater risk for cardiovascular disease, both heart disease and cerebrovascular events, with a relative risk of 1.6 (Islam et al, 2012a). Treatment of HIV reduces the risk of HIV-associated dementia (HAD) (Lescure

et al, 2011). The incidence of non-AIDS-defining cancers including liver, anal, oropharyngeal, and lung cancers, Hodgkin lymphoma, and melanoma is higher in HIV-infected persons than in matched controls (Bedimo et al, 2009). ART has been shown to be protective against development of HIV-associated malignancies (Guiguet et al, 2009). Another significant benefit to treatment is the prevention of sexual transmission of HIV. Lower levels of virus in the plasma are associated with lower levels in the genital secretions (Guiguet et al, 2009). Level of plasma virus load correlates with risk of HIV transmission in serodiscordant couples (Quinn et al, 2000; Tovanabutra et al, 2002).

One advancement in treatment has been the use of genetic testing to identify resistance-associated mutations in a given individual's HIV virus. Over 100 mutations involved in drug resistance have been described, and testing results are interpreted via one of the rule-based interpretation systems available on the Internet or through expert advice (Tang et al, 2012; Johnson et al, 2013). These data can predict the response to drug therapy including combinations in the range of 50% to 80% (Frentz et al, 2010). Given the limited resources in many countries with high rates of HIV infection, genotyping is not available for many infected people. Computational models have also been developed with results comparable to those of genotype testing; these models may be applicable in areas where genotyping is not available (Revell et al, 2013). Other testing for genetic variation in the CCR5 (R5) coreceptor is used to guide therapy with the drug maraviroc, a CCR5 antagonist, to help predict response and guide prescribing (Poveda et al, 2012). This can be used instead of the co-tropism receptor assay, which involves putting genetic sequences from the *env* gene of the virus into a vector and assessing for infection of cells expressing either the CXCR4 or the CCR5 co-receptor (Whitcomb et al, 2007).

Classes of currently available medications include the following (Fig. 15-15):

1. Nucleoside or nucleotide reverse transcriptase inhibitors (NRTIs) act via two mechanisms: (1) as "chain terminators" that block viral DNA elongation, stopping addition of further nucleosides, and (2) by competition or binding of the reverse transcriptase.
2. Non-nucleoside reverse transcriptase inhibitors (NNRTIs) act only by competition or binding of reverse transcriptase.
3. Protease inhibitors act by binding the aspartic protease, critical for post-translational processing of the polyprotein products into

POSSIBLE SITES OF INTERVENTION IN THE INHIBITION OF HIV REPLICATION

Figure 15-15. Antiretroviral therapy for human immunodeficiency virus (HIV): possible sites of intervention for drug therapy. (From Vella S, Florida M. HIV therapy: antiviral therapy. In: Cohen J, Powderly SF, Berkley SF, et al, editors. Infectious diseases. 2nd ed, vol. 2. Edinburgh: Mosby; 2004. p. 1387–98.)

the functional core proteins and viral enzymes. Inhibition of this step results in the release of immature, noninfectious viral particles. Protease inhibitors are also effective against chronically infected cells.

4. Integrase strand transfer inhibitors (INSTIs) block the enzyme integrase, used to integrate HIV viral DNA into the DNA of the host cell. Blocking integrase prevents HIV from replicating.
5. CCR5 antagonists block attachment to CCR5. These drugs are effective and durable only if the HIV molecule uses CCR5 and not CXCR4; thus receptor tropism screening is required before use (Thompson et al, 2012). A faster method of genetic tropism testing can also be used (Vandekerckhove et al, 2011).
6. Fusion inhibitors disrupt conformational changes in gp41 that drive membrane fusion.

Guidelines for the use of antiviral agents in HIV-1-infected adults and adolescents are available from the NIH on the aidsinfo.nih.gov website (U.S. Department of Health and Human Services Panel on Guidelines for Adults and Adolescents, 2013) and have also been published (Thompson et al, 2012). A synopsis of the treatment guidelines including level of evidence is as follows:

- ART should be started regardless of CD4 count. (For CD4 count below 350/ μ L, AI; for CD4 count between 350 and 500/ μ L, AII; and above 500/ μ L, BIII.)
- ART should be given during the acute phase of primary HIV infection regardless of symptoms (BIII).
- ART should be started within 2 weeks in persons with opportunistic infections (A1a).
- ART is recommended in HIV-infected persons with TB and should be started within 2 weeks of TB treatment when the CD4 count is below 50/ μ L and within 8 to 12 weeks for higher CD4 counts (A1a).
- Genotypic testing is recommended to guide therapy in ART-naïve patients. This includes testing in reverse transcriptase and protease genes; this may also be done when INSTI resistance is a concern (CIII). Gene therapy should also be used to guide a suboptimal response to therapy (AIII).
- A coreceptor tropism assay should be performed before starting a CCR5 receptor inhibitor.

As of the 2013 update, there were more than 20 approved antiretroviral drugs in the six classes just listed. Current treatment regimens for initial ART therapy consist of a combination of two NRTIs plus a third agent: an NNRTI, a ritonavir-boosted protease inhibitor, an INSTI, or an entry inhibitor (Thompson et al, 2012). Current regimens for first therapy and level of evidence for their use are as follows:

- Efavirenz/tenofovir disoproxil fumarate/emtricitabine (EFV/TDF/FTC), level AI
- Ritonavir-boosted atazanavir plus tenofovir disoproxil fumarate/emtricitabine (ATV/r + TDF/FTC), level AI
- Ritonavir-boosted darunavir + tenofovir disoproxil fumarate/emtricitabine (DRV/r + TDF/FTC), level AI
- Raltegravir + tenofovir disoproxil fumarate/emtricitabine (RAL + TDF/FTC), level AI

Postexposure Prophylaxis

Occupational Exposure for Health Care Providers. The incidence of exposure incidents among hospital-based health care workers is estimated at 384,00 per year, or 1 in 10 health care providers with an exposure per year (Panlilio et al, 2004). An exposure that might put a health care provider at risk is defined as a percutaneous injury such as a needle stick or cut with a sharp object, or contact with mucous membrane or nonintact skin (e.g., contact between exposed skin that is chapped or abraded or affected by dermatitis and blood, tissue, or other body fluids that are potentially infectious). In addition to blood and visibly bloody bodily fluids, other potentially infectious fluids that may be encountered by a health care provider are CSF, synovial fluid, pleural fluid, peritoneal fluid, pericardial fluid, and amniotic fluid. Semen and vaginal secretions are also infectious but have not been implicated in the occupational transmission of HIV. The average risk of HIV

transmission with a percutaneous exposure is 0.32%, or one infection for every 325 exposures to a documented HIV-infected person (Bell, 1997; Henderson, 2012). The risk is estimated to be less for mucosal membrane exposures, at 0.03% or one infection for every 3300 exposures (Ippolito et al, 1993; Henderson, 2012).

Several factors are known to influence the inoculum risk. The amount of virus in the exposure comes from the concentration of virus in the fluid and the volume of fluid in the exposure. Volume increases with needle size and depth of penetration; thus hollow-bore needles carry a higher amount of virus than solid suture needles (Bennett and Howard, 1994). The patient's viral load is also important; circulating viral load is highest during the initial stage near the time of seroconversion and in advanced stages near death. A review of factors for increased risk of infection done by the CDC identified four that increased risk: deep as opposed to superficial exposure (odds ratio [OR] 15, 95% CI 6 to 41), visible blood on the injuring device (OR 6.2, 95% CI 2.2 to 21), prior placement of the injuring device in an artery or vein (OR 4.3, 95% CI 1.7 to 12), and patient dying within 2 months of the exposure (preterminal disease) (OR 5.6, 95% CI 2 to 16) (Panlilio et al, 2005).

Standard Precautions were introduced by the CDC in 1996. Methods such as announcing transfer of sharps and double gloving, among other precautions, are recommended (Panlilio et al, 2005; Siegel et al, 2007). Immediate steps after exposure are washing the wound or skin site with soap and water, flushing exposed mucous membranes with tap water, and rinsing exposed eyes with sterile water or a commercial eye irrigant (tap water is an acceptable alternative). If the infectious status of the source is not known, the source should be evaluated for HIV and hepatitis B and C. If the source is known to have HIV but has undetectable serum viral load, postexposure prophylaxis (PEP) should still be given because of the risk of infection from latently infected cells (Furtado et al, 1999). The exposed health care worker should be assessed for tetanus and get a booster of tetanus, diphtheria, and acellular pertussis booster if indicated (Henderson, 2012). The biologic effectiveness of postexposure chemotherapy has been demonstrated in a study that found that postexposure treatment with zidovudine was associated with an 81% reduction in the risk of infection (Cardo et al, 1997).

Previous treatment regimens recommended two or three drugs as therapy depending on the risk stratification (Panlilio et al, 2005). The 2013 update now recommends three medications to start treatment: emtricitabine (FTC) plus tenofovir (TDF) (these can be given as the combination pill Truvada) plus raltegravir (RAL). The guidelines also specify the following:

1. Persons receiving PEP should complete a full 4-week regimen.
2. If the source is determined to be HIV negative, PEP should be discontinued and no further testing is indicated.
3. PEP should be initiated as soon as possible, preferably within hours, and follow-up should occur within 72 hours.
4. Follow-up at a minimum should include HIV testing at baseline and at 6 weeks, 12 weeks, and 6 months (baseline, 6 weeks, and 4 months if a p24 antigen antibody test is used). To assess for toxicity of the medications, complete blood count and renal and hepatic function tests at baseline and 2 weeks should be performed.

Management of Sex Partners of Infected Persons

HIV-infected patients should be encouraged to notify their partners and to refer for counseling and testing. If patients are unwilling to notify their partners, physicians or health department personnel use confidential partner notification procedures. Partners who were exposed to genital secretions and/or blood of an HIV-infected partner in the preceding 72 hours should be offered PEP.

Preexposure Prophylaxis

Preexposure prophylaxis is the treatment of an uninfected person before he or she has sexual contact with an HIV-infected partner. In July 2012 the FDA approved daily oral tenofovir disoproxil fumarate

300 mg (TDF) and emtricitabine 200 mg (FTC) (Truvada [Gilead, Foster City, CA]) to reduce the risk of HIV transmission, including in both heterosexuals and MSM. Data come from several large-scale trials that showed benefit ([Grant et al, 2010](#); [Baeten et al, 2012](#); [Thigpen et al, 2012](#)), but not all trials have shown a benefit ([Van Damme et al, 2012](#)). Also, one of the trials raised concerns about decline in bone mineral density associated with taking the drug ([Thigpen et al, 2012](#)). Other side effects are impairment of renal and liver function. There are multiple other barriers to the effective use of preexposure prophylaxis in addition to the side effects of the

drugs, including the need for strict adherence to the regimen for the drug to be effective, additional testing to monitor HIV status, and knowledge of the HIV status of the partner ([Steinbrook, 2012](#)). A recent trial of prophylaxis in MSM indicated that adherence was good (87%) and side effects were not different from those of placebo ([Grohskopf et al, 2013](#)). **A complementary approach to preexposure prophylaxis is treatment for prevention, in which the infected partner is treated to try to prevent transmission to the uninfected partner.** A review of available trials indicates this can also be an effective strategy ([Baggaley et al, 2013](#)).

Renal Infections

Mycobacterial infection of the kidney is detected at autopsy in 6% to 23% of AIDS patients, and a significant number had no symptoms before death (Shindel et al, 2011a). Persons with HIV infection are more likely to develop clinical TB if infected, including renal and other extrapulmonary disease (Weiss et al, 1998). Treatment for TB may include rifampin, which induces cytochrome P450 and lowers concentrations of protease inhibitors and NNRTIs. HIV patients being treated for TB should be monitored carefully, and drug levels may have to be monitored and adjusted (Sterling et al, 2010). Other renal infections that occur in AIDS include CMV (van der Reijden et al, 1989) and *Aspergillus* and *Toxoplasma* infections. Abscesses may develop that require drainage, percutaneous or open, or nephrectomy.

Prostatitis

Prostate infection may be more common in men with HIV. One study of 209 hospitalized men with HIV reported bacterial prostatitis in 8%, with the incidence increasing from 3% in men with asymptomatic HIV infection to 14% in patients with AIDS (Leport et al, 1989). Most of the men were symptomatic with fever and urinary symptoms; prostate tenderness was not universal but was found on examination in 41%. Prostatitis is usually caused by *E. coli*, but in HIV-infected men many other organisms can cause prostate infection, including *S. aureus*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Serratia marcescens*, *Salmonella* Typhi, *Mycobacterium tuberculosis* and *Mycobacterium avium intracellulare*, and CMV (Weinberger et al, 1988; Benson and Smith, 1992). Fungal infections also can cause prostatitis, particularly in immunocompromised patients with T-cell counts below 200 cells/ μ L. Organisms include *C. albicans*, *Aspergillus fumigatus*, *Cryptococcus neoformans*, and *Histoplasma capsulatum* (Santillo and Lowe, 2006).

In men with HIV, cultures should be performed not only for the usual bacteria, but also for more atypical organisms including aerobes, anaerobes, fungi, and *M. tuberculosis* (Heyns and Fisher, 2005). The usual treatment in these men is a 4- to 6-week course of antimicrobials; in men with HIV, consideration should be given to low antimicrobial suppression for some time to reduce the risk of recurrence (Santillo and Lowe, 2006). In patients who are already being treated with ART and still persistently immunocompromised, lifetime suppressive antimicrobials have been recommended to reduce risk of progression to prostatic abscess (Lee et al, 2001). Prostate abscess can develop from relapsing or untreated infection and usually occurs in more severely immunocompromised patients. The incidence of prostate abscess in men with HIV has been reduced by use of ART, which has decreased the incidence of opportunistic infections (Murphy et al, 2001), and also by the use of long-term antibiotics in HIV men with bacterial or atypical urinary tract infections (UTIs). Diagnosis is made by transrectal ultrasound or computed tomography (CT) scan. It is important to prevent progression to sepsis by using broad-spectrum antimicrobials and performing surgical drainage.

Urinary Tract Infection

In a prospective study of urine cultures in a group of HIV-positive men, 30% of the group with CD4 counts below 200 had an episode of bacteriuria, which was significantly greater than in the group with CD4 counts of 200 to 500 (11%) and above 500 (0%) (Hoepelman et al, 1992). There was no association with age or practice of anal intercourse. Of the episodes of bacteriuria, 42% were asymptomatic. The incidence of bacteriuria also increases with progression to AIDS (De Pinho et al, 1994). The bacteria found in UTI in HIV-infected individuals may be different as well. Data from a single site showed that over a 9-year period, the most common organism causing UTI in HIV-infected patients, men and women, was *Enterococcus* (26%), whereas in uninfected controls it was *E. coli* (64.8%). *Proteus* was also found five times more often in the HIV-infected group (Schonwald et al, 1999). In severely immunocompromised

patients, unusual organisms may cause UTIs, including CMV (Benson et al, 1988). The mucosa may appear normal with a CMV infection, and deep biopsies may be needed to diagnose CMV interstitial cystitis (Whitaker et al, 2008). Other urinary infections include fungi such as *Cryptococcus*, *Candida*, or *Aspergillus* (Kiartiburanakul et al, 2004); other viruses including erythrovirus B19 (parvovirus B19) (Christensen et al, 2001) and adenovirus; and parasites such as *Toxoplasma gondii* and *Mycobacterium* (Heyns et al, 2009).

Overall, the incidence of bacteriuria does not appear to be greater in women with HIV but can be associated with the amount of viral load (Park et al, 2002). The management of UTI may be complicated by the concomitant use of other antibiotics for prophylaxis for other infections in HIV-infected patients. The use of co-trimoxazole as prophylaxis against pulmonary infection did not reduce the risks of UTI in a series of HIV-positive patients (Evans et al, 1995). However, the use of the other antibiotics may select out for antibiotic resistance. Among the bacterial isolates found in 350 episodes of symptomatic UTI in HIV-infected subjects, 29 of 36 *E. coli* isolates were multidrug resistant. Overall, 83% of bacterial isolates were resistant to trimethoprim-sulfamethoxazole (Vignesh et al, 2008). These findings should help inform empirical therapy for symptomatic UTI in these patients.

Testis, Epididymis and Seminal Vesicles

HIV in semen is the main vector for transmission and can persist despite high loads of ART (Roulet et al, 2006). The interstitium of the testis contains cells that have the receptors and coreceptors CXCR4, CCR5, CD4, and DC-SIGN, and is permissive to HIV infection. These cells appear to be macrophages (Roulet et al, 2006). The seminal vesicles also appear to be a reservoir for HIV, again with infection located in macrophages (Deleage et al, 2011).

The most common intrascrotal pathology in men with HIV/AIDS is testicular atrophy. This can arise from endocrine imbalances, febrile episodes, malnutrition, testicular infections, and toxic effects of therapy (Leibovitch and Goldwasser, 1994). A correlation has also been shown with body mass index (BMI); underweight HIV patients were 3.5 times more likely to have testicular atrophy on autopsy (Mhawech et al, 2001). The histology in men with HIV is peritubular interstitial inflammation, interstitial fibrosis, and thickening of the basement membrane (De Paepe et al, 1989). Spermatogenesis is decreased and maturation arrest is observed (Leibovitch and Goldwasser, 1994). HIV itself is thought to be cytotoxic to germ and Sertoli cells; on average, 30% of germ cells are infected (Shevchuk et al, 1998).

The testes may also be directly infected by opportunistic infections. Up to 39% of examined testes in autopsy series may have an opportunistic infection (Leibovitch and Goldwasser, 1994). The most common pathogens are CMV, *T. gondii*, and *M. avium intracellulare* (Lo and Schambelan, 2001). Treatment requires initial antibiotic therapy followed by a period of maintenance suppression, particularly if *Salmonella* is identified as the causative organism (Shindel et al, 2011a). Patients with AIDS are also prone to develop tuberculous epididymitis (Heyns et al, 2009). As a result of atrophy, infection, or other insult, testicular failure can occur. In combination with extratesticular causes, testosterone levels fall with progressive HIV disease (Lo and Schambelan, 2001; Moreno-Perez et al, 2010a).

Renal Function

Many factors affect renal function in patients with HIV/AIDS (Miro et al, 2012). HIVAN has received considerable attention because of the rapid clinical decline in these patients, the progression to irreversible renal failure, and the predilection for African Americans (Pardo et al, 1984; Rao et al, 1984). The classic clinical presentation is that of rapidly progressive azotemia with severe proteinuria, often nephrotic range, and little or no peripheral edema. The initial pathologic lesions described were global or focal segmental glomerulosclerosis (FSGS). Other features added to the description

include collapse of glomerular capillary loops, called “collapsing glomerulopathy” (Weiss et al, 1986). A recent review of a large case series of kidneys with HIVAN also described a new variant, termed the “fetal variant” because histologically it resembles a fetal glomerulus (Wearne et al, 2012). There appears to be a spectrum of histologic findings now associated with HIVAN, making the consensus definition in flux (Wearne et al, 2012).

The pathogenesis of HIVAN involves infection of renal epithelial cells by HIV virus, including podocytes, glomerular parietal epithelial cells, and tubular cells (Leventhal and Ross, 2008). Infection can be by cell free virus or by transfer of virus from infected T cells to renal tubular epithelial cells (Chen et al, 2011). The *vpr* and *nef* genes of HIV-1 are the most responsible for inducing HIVAN (Leventhal and Ross, 2008). Recently the genetic predisposition to HIVAN has been characterized. African-Americans carrying two variants of the *APOL-1* gene are at very high risk to develop HIVAN. These genes encode a secreted lipid binding protein called *apolipoprotein-1* (*apoL1*). The variants G1 and G2 are common in African chromosomes but absent in European chromosomes; these variants lyse trypanosomes, including *Trypanosoma brucei rhodesiense*, which causes African sleeping sickness (Genovese et al, 2010). Thus, these loci are thought to be selected out in this population. The presence of these two genes together increases the risk by 29-fold, resulting in a 50% risk of development of HIVAN in untreated individuals (Kopp et al, 2011) as compared with a 12% baseline risk (Shahinian et al, 2000). FSGS found in individuals with the two risk genes also occurs at an earlier age and progresses much more rapidly (Kopp et al, 2011). There also may be a contribution from the myosin heavy chain gene 9 (*MYH9*), which is a locus adjacent to the *APOL-1* gene on chromosome 22 and has been implicated in rare kidney disease producing glomerulosclerosis and podocyte effacement (Hays and Wyatt, 2012). Podocyte specific deletion of *Myh9* predisposes mice to renal injury (Johnstone et al, 2011). *APOL-1* and *MYH9* are likely contributors to HIVAN, but not the only contributors (Kopp et al, 2008).

The incidence of HIVAN can be decreased by treatment to reduce the viral load (Lucas et al, 2004). The study by Wearne and colleagues from South Africa (Wearne et al, 2012) included findings from a time when ART had not yet been endorsed or provided by the South African government. Therefore data are available on the untreated natural history of HIVAN. The 50% survival of those patients with HIVAN without ART was 4.47 months. The use of ART, no matter when started, reduced the mortality by 57%. Patients with better estimated glomerular filtration rate (eGFR) at presentation had better outcomes (adjusted hazard ratio [AHR] 0.72).

Voiding Dysfunction

Early series on voiding dysfunction in HIV-positive patients reported on neurogenic bladder in patients largely with AIDS and neurologic complications (Gyrtrup et al, 1995; Menéndez et al, 1995). Detrusor areflexia was commonly seen in patients with AIDS (Khan et al, 1992), but more patients with non-AIDS HIV had detrusor hyperreflexia (overactivity) (Kane et al, 1996). With the use of ART, patients are living longer and having less severe complications, and therefore it is expected that there will be an increase in incidence of voiding dysfunction as a result of aging in this group. In an Internet survey of MSM, HIV status was an independent risk factor for bothersome lower urinary tract symptoms (LUTS), and a history of AIDS was a risk factor for severe disease. Other risk factors for moderate but not severe LUTS were UTI, prostatitis, and gonorrhea. Although the cause of the association is not known, this study raised the question as to whether a direct toxic effect of the virus or ART leads to LUTS (Breyer et al, 2011).

Hematuria

A study from 1995 reviewed the records of 1326 patients with HIV in the U.S. Air Force. Urinalysis was performed and found a high rate of hematuria at 25%. Of the 67 patients with hematuria who underwent evaluation, management was affected in three patients

(4%). The recommendation at that time was that in young asymptomatic HIV-positive patients with microscopic hematuria, a urologic evaluation could be omitted (Cespedes et al, 1995). Of note in this study is that grade 1 hematuria was defined as 1 to 4 red blood cells (RBCs) per HPF; given the current definition of microhematuria as 3 or more RBCs per HPF, some of these patients who were diagnosed with microhematuria might not be diagnosed according to current criteria. Of the men with renal cell cancer in a recent series of patients with HIV, 44% had hematuria on presentation (Gaughan et al, 2008). Given the greater life expectancy of patients infected with HIV on ART, hematuria in the setting of HIV infection should be evaluated as in other individuals.

Erectile Dysfunction

The prevalence of mild, moderate, and severe erectile dysfunction (ED) is reported as being higher in HIV-infected than uninfected men for all decades of age. On multivariate analysis, HIV infection is the strongest predictor of ED, with an OR of 42.26 ($P < .001$) (Crum et al, 2005; Ende et al, 2006; Crum-Cianflone et al, 2007; Zona et al, 2012). Other studies have shown that progression to AIDS also leads to greater ED (Shindel et al, 2011b). ED is common in HIV-infected men under age 50, reported as 50% of infected men younger than age 30 years, 48% of those aged 31 to 40 years, and 53% of those aged 41 to 50 years (Zona et al, 2012). HIV also leads to an increased risk and earlier onset by 10 to 15 years of other comorbidities including coronary disease, diabetes, and bone fractures (Guaraldi et al, 2011). Thus, ED is thought to be one of the manifestations of an early aging phenomenon that is being seen in HIV-infected individuals. Other factors also influence the development of ED in this population, including depression (Crum-Cianflone et al, 2007), psychological distress associated with changes in body composition (lipodystrophy) (Guaraldi et al, 2012), hypogonadism (Crum et al, 2005; Zona et al, 2012), and diabetes (Shindel et al, 2011b). Endothelial dysfunction as measured by brachial artery flow-mediated dilation was not associated with ED in men with HIV (Guaraldi et al, 2012).

The role of ART in the development of ED in men with HIV is uncertain. Several studies have shown an association with ART, including duration of ART (Moreno-Perez et al, 2010b), and particularly protease inhibitors (Martinez et al, 1999; Lamba et al, 2004; Asboe et al, 2007). Other studies have not confirmed these associations (Ende et al, 2006; Zona et al, 2012). One consideration in treating ED in men with HIV is the possible interaction of phosphodiesterase type 5 (PDE5) inhibitors and antiretroviral medications. PDE5 inhibitors depend on CYP3A for clearance, and all protease inhibitors and NNRTIs are inhibitors of CYP3A to some extent (Rosen et al, 2006). This can lead to a significant increase in the serum dose of PDE5 inhibitors, and therefore they should be started at the lowest dose possible in patients taking these ART medications (Merry et al, 1999).

Stones and Human Immunodeficiency Virus

One of the complications of some medications for treatment of HIV is stone formation. The protease inhibitors specifically may cause stone formation. Indinavir can form crystals in the urine (Kopp et al, 1997). The incidence of indinavir stones is reported to be as high as 22% (Brodie et al, 1998). The risk has been reported to be greater in patients with hepatitis (Malavaud et al, 2000) or hemophilia (Brodie et al, 1998). Indinavir stones are typically radiolucent on both plain film and CT scan but can also be mixed with calcium and appear radiopaque (Sundaram and Saltzman, 1999). Newer inhibitors including lopinavir, atazanavir, amprenavir, and nelfinavir have also been associated with the development of stones, but with less frequency than reported for indinavir (Shindel et al, 2011a). The incidence of stones with atazanavir was 0.97% in one series (Couzigou et al, 2007). One possible risk factor for atazanavir stones is the discontinuation of tenofovir. Concomitant administration of tenofovir lowers circulating levels of atazanavir, so discontinuation increases plasma levels;

this was thought to play in a role in several cases of atazanavir stones (Fabbiani et al, 2011).

Hydration after taking protease inhibitors is suggested as means to reduce the risk of stone formation (Daudon et al, 1997). In patients with protease stones and in whom conservative management is possible as a first-line step, discontinuation of the drug and hydration should be tried. Success with these measures approaching 70% has been reported (Kohan et al, 1999). Patients with HIV can have other conditions that contribute to stone formation including dehydration with high specific gravity, low pH, hyperoxaluria, hypercalciuria, and hypocitraturia (Gagnon et al, 2000; Nadler et al, 2003). One other type of stone reported to be more common in HIV patients is ammonium acid urate stones, possibly reflecting chronic diarrhea and malnutrition of chronic disease (Nadler et al, 2003).

Human Immunodeficiency Virus and Neoplasms

In the earlier history of HIV infection, the predominant oncologic problems were AIDS-defining cancers, Kaposi sarcoma (KS), non-Hodgkin lymphoma, and, in women, invasive cervical cancer. With the advent of more effective therapies, ART has markedly improved life expectancy, turning HIV into a chronic disease. The emphasis has shifted to non-AIDS-defining cancers (Bonnet et al, 2009). Overall, patients with HIV compared with the general population still have a greater risk to develop not only non-AIDS-defining cancers with a viral pathogenesis but also non-virus-related cancers, estimated at a twofold risk in a recent study (Albini et al, 2013). Several factors have been suggested to explain this increased risk, including high-risk behaviors such as tobacco smoking, which is two to three times more prevalent in HIV-infected patients (Rahmanian et al, 2011); immunodeficiency (Grulich et al, 2007); inflammation (Borges et al, 2013); and age itself, because people are living longer with HIV infection (Albini et al, 2013). For the urologist, KS has the greatest relevance of the AIDS-defining cancers, given the possibility of KS lesions on the penis. There are increasing data regarding the rates and clinical course of non-AIDS-defining urologic malignancies.

Kaposi Sarcoma

Kaposi sarcoma was described in 1872 by Moritz Kaposi, who described three cases of fatal pigmented hemangiosarcomas in elderly men (Ruocco et al, 2013). Four forms are described: classic as described by Kaposi; an African endemic form occurring in young black men aged 25 to 40; an iatrogenic form first seen in the 1970s in patients on immunosuppressive therapy; and first reported in 1981 the form of KS in young homosexual men called the “epidemic form” (Hymes et al, 1981; Ruocco et al, 2013). KS is the second most common tumor in HIV-infected patients worldwide (Martellotta et al, 2009). However, the incidence of KS has decreased dramatically since the advent of the use of ART. In one recent prospective study, no new cases were noted in the period 1997 to 2000 (Speeckaert et al, 2011). Patients with KS typically have a CD4 cell count below 150 cells/mm³ and a viral load higher than 10,000 copies/mL (Gallafent et al, 2005). A cluster of patients having KS despite being on ART, and with CD4 cell counts above 300 cells/mm³ and viral loads below 300 copies/mL for at least 2 years, has been reported (Maurer et al, 2007).

The causative agent found in more than 90% of KS patients of all four types is human herpesvirus 8 (KSHV/HHV-8), a double-stranded DNA virus (Chang et al, 1994; Buonaguro et al, 1996). HHV-8 is now considered a necessary condition for the development of KS, but not all persons with HHV-8 get KS, and genetic, immunologic, and environmental factors are thought to be required as cofactors for KS to develop (Ruocco et al, 2013). KSHV infection leads to proliferation of both endothelial and spindle cells, the predominant cell type in KS, and angiogenesis (Martellotta et al, 2009; Ma et al, 2013). KS typically manifests with disseminated pigmented skin lesions, a few millimeters to several centimeters, from pink to purple or brown, often associated with edema and

lymph node and visceral involvement in up to 50% of patients. Other common sites of involvement are the oral cavity, gastrointestinal (GI) tract, and lungs (Mitsuyasu, 1993). The prognosis depends on the extent of the tumor, status of the immune system by CD4 count, and presence of systemic illness. The 3-year survival for patients with good risk is 80% to 88%, and for those with poor risk factors it is 53% (Nasti et al, 2003). Treatment depends on the type and is either local or systemic (Curatolo et al, 2012; Ruocco et al, 2013). For systemic therapy, one mainstay for epidemic KS is ART, which can produce a remission rate of 35% to 50% (Nguyen et al, 2008; Ruocco et al, 2013). Lesions typically start to decrease in size a few weeks to months after the initiation of treatment (Spano et al, 2008). KS may flare dramatically initially after the initiation of ART in what is called the *immune reconstitution inflammatory syndrome* (IRIS), seen in HIV-positive patients with initial low CD4 counts and high viral load (Leidner and Aboulafia, 2005). Onset of IRIS is as early as 3 weeks, with a mean onset of 5 weeks, and the syndrome can be fatal (Leidner and Aboulafia, 2005). First-line chemotherapy for advanced disease is liposomal anthracyclines (pegylated liposomal doxorubicin, daunorubicin citrate liposome DNX). Pegylated liposomes accumulate preferentially in highly vascularized KS lesions and are more effective than conventional chemotherapy regimens and with fewer side effects (Krown et al, 2004). Second-line therapy is paclitaxel or docetaxel (Lim et al, 2005; Cianfrocca et al, 2010).

Non-AIDS-Defining Urologic Malignancies

Testicular Tumors. The risk of testis tumors in early studies was reported to be 20 to more than 50 times greater in men with HIV than in uninfected men, and in general for seminoma. Later studies looking at men with HIV infection but after the development of ART have put the relative risk at a still significant level but much lower. Powles and colleagues found a relative risk for nonseminomatous germ cell tumors (NSGCTs) and seminoma of 4.36 (95% CI 2.71 to 6.55) and 5.45 (95% CI 3.35 to 8.10) (Powles et al, 2003). In a review of more than 260,000 men in the United States from 1980 to 2003, the risk for seminoma was 1.9 (95% CI 1.6 to 2.2) and there was no increased for NSGCTs (Goedert et al, 2007). An increased risk of 3.11 (95% CI 1.48 to 6.52) was recently reported from an Italian cohort, with no distinction between seminoma and nonseminoma tumors (Albini et al, 2013). The treatment for HIV-positive men with testes germ cell tumors is the same as for uninfected individuals (Powles et al, 2003). HIV-infected men are also at risk for testicular non-Hodgkin lymphoma, which may be disseminated at time of presentation, but tend to have the same response to therapy as uninfected individuals (Heyns et al, 2009).

Prostate Cancer. The relative risk of prostate cancer in men with HIV compared with uninfected individuals has been reported as either being no different or being even less, at 0.70 (Grulich et al, 2007; Bedimo et al, 2009; Albini et al, 2013). It has been postulated that ART may have a protective effect on prostate cancer independent of effect on increasing the CD4+ count (Chao et al, 2012). Radiotherapy in HIV-positive men is not associated with an increase in complications or effect on CD4 count (Ng et al, 2008). An increase in infectious complications with radical prostatectomy may be seen in patients with lower CD4 counts and higher viral loads, but no other adverse perioperative complications or differences in response to therapy (Huang et al, 2006). In a series of patients undergoing robot-assisted laparoscopic radical prostatectomy for prostate cancer, patients infected with HIV had a higher rate of transfusion and ileus compared with men without HIV; no other complications were different in the two groups, and prostate-specific antigen (PSA) was undetectable at 8 months in all HIV-positive men (Silberstein et al, 2010). PSA levels do not appear to be different in men based on their HIV status (Vianna et al, 2006; Pantanowitz et al, 2008). HIV-positive patients are reported to have a greater likelihood of a positive prostate biopsy compared with uninfected men (OR 3.9, 95% CI 1.3 to 11.5) (Hsiao et al, 2009), but the Gleason score on biopsies is not different (Pantanowitz et al, 2008). Overall, the evaluation and treatment of prostate cancer in patients

with HIV do not appear to be significantly different from those in uninfected men (Levinson et al, 2005). Given that the median survival after starting ART is estimated to be over 13 years (Walensky et al, 2006), patients with HIV should be screened and treated as uninfected men.

Kidney Cancer. An increased risk of renal cell carcinoma and HIV infection has been reported. In a study of more than 300,000 adults aged 15 to 69 years with HIV/AIDS in multiple geographic locations in the United States, compared with the expected population-based incidence rates, kidney cancer was 1.5 times more likely in the HIV population, similar to another large study of more than 444,000 patients (Frisch et al, 2001; Grulich et al, 2007). There was no increase in risk with progression to AIDS, arguing against immunosuppression as a contributing factor (Frisch et al, 2001). Much higher risks of developing renal cell cancer in HIV infection were reported in a single-site series from Cleveland (United States)—an increased risk of 8.5 times, as well as presentation 15 years younger than expected (Baynham et al, 1997)—and from Uganda (Africa), reporting a relative risk of up to 16 times (Mbulaiteye et al, 2006). A case series of nine men with renal cell carcinoma found diagnosis at a median age of 48, no association with immunosuppression, and a clinical presentation or response to treatment that appeared similar to that of uninfected individuals (Gaughan et al, 2008). The differential diagnosis of renal mass in an HIV-infected person should also include lymphoma.

Penile Cancer. The relative risk of penile cancer is reported to be approximately four times higher than in men without infection (Frisch et al, 2001; Grulich et al, 2007). Men with HIV have a high prevalence of high-risk HPV types, 16 and 18, in the anus, penis, and mouth, without evidence of any lesions in these areas (Sirera et al, 2006). This occurs in both MSM and heterosexual men (Videla et al, 2013). The risk of penile cancer increases the closer a man is to having AIDS or the longer he has had AIDS (Chaturvedi et al, 2009). Although squamous cell cancers can be more aggressive in HIV-positive individuals (Nguyen et al, 2002), early lesions such as penile intraepithelial carcinoma can still respond to treatment with local therapy (Ramoni et al, 2009).

Bladder Cancer. In large series reporting the incidence of cancer in HIV-positive patients compared with those without infection, bladder cancer is not more frequent than in uninfected persons (Frisch et al, 2001; Grulich et al, 2007; Mbulaiteye et al, 2006). A suggestion of a reduced risk has been reported (Layman and Engels, 2008). A case series of patients with bladder cancer and HIV indicated no difference in clinical course or response to treatment (Gaughan et al, 2009). One possible difference in treatment of HIV-positive patients is to use caution in deciding to use intravesical bacille Calmette-Guérin (BCG). The effectiveness of BCG is dependent on a functioning immune system, and therefore the agent is not typically used in immunocompromised patients. There is the theoretic risk of disseminated infection. One case report has documented bilateral interstitial pneumonitis in an HIV-infected patient after intravesical therapy with BCG (Kristjansson et al, 1993). However, in the case series by Gaughan and colleagues, one of their HIV patients received BCG without complications (Gaughan et al, 2009).

KEY POINTS

- Patients with urethritis need to be treated for both gonorrhea and chlamydia. In addition to microscopic examination of urethral discharge, urine should be sent for nucleic acid amplification testing for both gonorrhea and chlamydia. Urethral swab is no longer indicated.
- Most genital ulcers in the United States are either herpes or syphilis, with most being herpes. Chancroid occurs in some parts of the United States, but donovanosis usually does not. LGV is increasing in incidence in MSM, including in the United States.
- Vaccines to prevent HPV-associated disease such as genital warts and anal cancer in both genders and cervical cancer in females are now available and recommended for men and women younger than age 26, preferably to start before onset of sexual activity.
- Testing for HIV is recommended in anyone with an STD or at risk of acquiring an STD.
- Treatment of HIV with ART is indicated in all infected persons regardless of CD4 count.
- HIV is becoming a chronic disease, and many of the associated problems are from aging and chronic disease instead of immunosuppression.

Cutaneous Diseases of the External Genitalia

Richard Edward Link, MD, PhD, and Theodore Rosen, MD

Introduction to Basic Dermatology

Dermatologic Therapy

Allergic Dermatitis

Papulosquamous Disorders

Vesicobullous Disorders

Noninfectious Ulcers

Infections and Infestations

Neoplastic Conditions

Benign Cutaneous Disorders Specific to the Male Genitalia

Common Miscellaneous Cutaneous Disorders

The diagnosis and treatment of cutaneous diseases of the external genitalia remain important elements of urologic practice. Often overlooked during formal urology residency training, this topic lies at the interface of multiple specialties, including urology, diagnosis of infectious diseases, rheumatology, allergy-immunology, and dermatology.

INTRODUCTION TO BASIC DERMATOLOGY

Dermatology is the clinical discipline focused on the normal biology and pathogenesis of diseases and disorders of the skin. The diagnosis of skin disease depends critically on the history and physical examination, with laboratory testing often relegated to a peripheral and confirmatory role. In many cases, visual inspection alone will suffice to narrow the diagnosis significantly. On the other hand, the skin has a limited repertoire of morphologic expression. Therefore one should not hesitate to perform a skin biopsy, when indicated, or to order a variety of laboratory investigations when needed to distinguish between two or more clinical mimics.

The skin is divided into three layers: the epidermis, dermis, and subcutaneous tissue. The epidermis, composed of stratified squamous epithelia, can vary in thickness from 0.05 to 1.5 mm depending on location. Melanocytes (pigment-producing cells) populate the lower layers of the epidermis. The dermis, composed of collagen, elastin, and reticular fibers, can be divided into two layers: the thin superficial layer (papillary dermis) and the thicker deeper layer (reticular dermis). Located within the dermis are mesenchymal structures, such as blood vessels and nerves. The bottom layer of the skin, known as subcutaneous tissue, is largely composed of fat.

Literally hundreds of cutaneous diseases exist that may involve the external genitalia. In addition, within each disease there may be significant variation in appearance and symptoms as the process for each condition evolves. For this reason, a methodical and systematic approach is essential to reach a rational diagnosis. The dermatologic history should focus on the duration, rate of onset, location, associated symptoms, family history, allergies, occupation, and previous treatment of the condition (Habif, 2004). Common symptoms include pruritus (itching), burning, stinging, and pain. The lack of symptoms, such as pain, can be important in arriving at the correct diagnosis and should therefore be noted.

The physical examination should address the distribution of primary and secondary skin lesions. **It is important to perform a thorough skin survey and not to focus solely on the area of affected genital skin.** Most skin conditions begin with a characteristic primary lesion that is an important key to diagnosis. A precise description of this lesion includes documenting its color (red,

brown, black, yellow, white, blue, or green) and morphology (macule, papule, plaque, nodule, pustule, vesicle, bulla, or wheal; Table 16-1) (Habif, 2004). Because of the mucosal nature of genital skin, papular and macular lesions may present as erosions in this area (Margolis, 2002). Secondary skin lesions develop as the skin condition evolves or are caused by scratching, rubbing, or superinfection. A secondary lesion should also be classified morphologically as a scale, crust, erosion, ulcer, atrophy, thickening, or scar (Table 16-2).

After gross morphology is determined, laboratory testing may serve to confirm the diagnosis. To identify cutaneous fungi such as dermatophytes and *Candida* species, potassium hydroxide (KOH) or periodic acid-Schiff staining may be applied to scraped or touched skin specimens. KOH dissolves keratin, leaving fungal hyphal walls prominently visible under the microscope. Likewise, Tzanck preparations may aid in identifying viral agents such as herpes simplex, varicella zoster, and molluscum contagiosum.

For difficult cases or those in which malignancy is suspected, skin biopsy may be indicated. A variety of techniques exist for this purpose, including curettage, punch, shave, and incisional and complete excisional biopsies. For small scrotal or phallic shaft lesions, these techniques can usually be performed in the office setting under local anesthesia. For larger lesions or those involving the urethral meatus, biopsy in the operating room is recommended. It is often possible to determine the correct diagnosis with a very small (2 to 3 mm) punch biopsy. The resultant defect can easily be closed with one or two 6-0 or 7-0 nylon sutures, thereby avoiding any substantial scar.

Additional diagnostic maneuvers that may prove invaluable in select situations include serologic testing (e.g., serologic tests for syphilis), culture (e.g., culture for *Pseudomonas aeruginosa*), and immunohistochemistry stains of biopsy specimens (e.g., examination for specific types of cytokeratins associated with different variants of lichen sclerosus).

DERMATOLOGIC THERAPY

Medical therapy for dermatologic conditions consists of a broad range of topical and systemic compounds.

For systemic therapy, useful drug classes include antibiotics, antifungals, antivirals, anti-inflammatories, and antipruritics. Less commonly used agents, including chemotherapeutic and biologic drugs (e.g., methotrexate, cyclophosphamide, adalimumab, etanercept, infliximab, and ustekinumab), immunosuppressants (e.g., azathioprine, cyclosporine, tacrolimus), and hydroxyurea, will be discussed within the specific disease entities.

TABLE 16-1 Primary Cutaneous Lesions

PRIMARY LESION	DESCRIPTION
FLAT	
Macule	A circumscribed, flat discoloration that may be brown, blue, red, or hypopigmented
ELEVATED, SOLID	
Papule	An elevated, solid lesion up to 0.5 cm in diameter of variable color. Papules may become confluent to become plaques
Nodule	A circumscribed, elevated solid lesion >0.5 cm in diameter
Plaque	A circumscribed, elevated , superficial, solid lesion >0.5 cm in diameter
FLUID-FILLED	
Vesicle	A circumscribed collection of free fluid ≤0.5 cm in diameter
Bulla	A circumscribed collection of free fluid >0.5 cm in diameter
Pustule	A circumscribed collection of leukocytes and free fluid (pus)
Wheal (hive)	A firm erythematous plaque resulting from infiltration of the dermis with fluid (may be transient)

From Habif TP. Clinical dermatology: a color guide to diagnosis and therapy. Edinburgh: Mosby; 2004.

TABLE 16-2 Secondary Cutaneous Lesions

SECONDARY LESION	DESCRIPTION
Scale	Excess dead epidermal cells that are produced by abnormal keratinization and shedding
Crust	A collection of dried serum and cellular debris (a scab)
Erosion	A focal loss of epidermis. Erosions do not penetrate below the dermoepidermal junction and they heal without scarring
Ulcer	A focal loss of epidermis and dermis, which heals with scarring
Fissure	A linear loss of epidermis and dermis with sharply defined, vertical walls
Atrophy	A depression in the skin resulting from thinning of the epidermis or dermis
Scar	An abnormal formation of connective tissue implying dermal damage

From Habif TP. Clinical dermatology: a color guide to diagnosis and therapy. Edinburgh: Mosby; 2004.

A lack of familiarity with cutaneous diseases affecting the genitalia may lower the threshold of urologists in prescribing systemic antibiotics for these conditions. Unfortunately, these agents carry significantly greater risks than topical preparations, including promotion of resistant organisms, interaction with other medications, and disruption of the normal bowel and vaginal flora. It is worth noting that alterations in bacterial flora or in their

antimicrobial susceptibility patterns may persist for protracted periods, thus emphasizing the need for truly appropriate antibiotic use (Jernberg et al, 2010). Similar caveats apply to systemic antifungal agents such as fluconazole, ketoconazole, and terbinafine. Superficial dermatophytes, such as those causing tinea cruris, generally respond well to diligent application of topical antifungal preparations. **Systemic antifungals are only indicated for very extensive cutaneous dermatophytosis, endemic mycoses with skin involvement, deep infection involving the hair follicles (Majocchi granuloma), or fungal infections in severely immunocompromised individuals (Leshner and McConnell, 2003).** In some cases, even in immunocompetent individuals, systemic antifungals are necessary to treat infections resistant to local therapy (Leshner, 1999). On the other hand, warnings have emphasized the need to avoid the routine use of some systemic antifungal medications (such as ketoconazole) for superficial cutaneous infections because of the unpredictable risk of life-threatening hepatotoxicity and adrenal insufficiency (U.S. Food and Drug Administration, 2013). Systemic anti-inflammatory agents, in particular the glucocorticosteroids (GCS), deserve additional attention. Oral GCS are absorbed in the jejunum with peak plasma concentrations occurring in 30 to 90 minutes (Lester, 1989). Despite short plasma half-lives of 1 to 5 hours, the duration of effect of GCS lasts between 8 and 48 hours, depending on the agent (Nesbitt, 2003). These drugs have **widespread anti-inflammatory effects.** They release neutrophils from bone marrow but they inhibit their movement to sites of inflammation in tissue. They also impair both T-cell activation and antigen presentation by dendritic cells (Nesbitt, 2003). **For short-term (≤3 weeks) treatment of dermatologic conditions such as allergic contact dermatitis (Feldman, 1992), a single morning dose of GCS is administered to minimize suppression of the hypothalamic-pituitary-adrenal axis (Myles, 1971).** Prednisone is generally the GCS of choice because of its low cost, intermediate duration of action, and variety of dosage forms, although methylprednisolone may be substituted to reduce the mineralocorticoid effects (Wolverton, 2001). **Longer-term treatment with systemic GCS may lead to a wide variety of adverse effects including osteoporosis, cataract formation, hypertension, obesity, hyperglycemia, aseptic necrosis of the femoral head, immunosuppression, and psychiatric changes (Nesbitt, 2003).** For this reason, the use of topical steroids (see later) is preferable to reliance on systemic GCS, whenever clinically feasible.

Topical preparations are the mainstay of therapy for a wide range of cutaneous diseases affecting the genitalia. Urologists tend to be less familiar with the use of these medications than are dermatologists. **Topical medications can be broken down into five general classes: emollients, anti-inflammatories, antibiotics, antifungals, and chemotherapeutic agents.**

Topical preparations include active ingredients and they also include a vehicle that determines the rate at which the active ingredients are absorbed by the skin. Emollients restore water and lipids to the epidermis and are useful for dry-skin diseases. Emollients should be applied to moist skin for maximal effect, such as after bathing. Preparations containing urea (e.g., Carmol, vanadine) or lactic acid (Lac-Hydrin, AmLactin) may be particularly potent hydrating agents (Habif, 2004). It has been noted that ceramides (combinations of a fatty acid and a sphingoid base), the main natural intercellular lipids in the outermost layer of skin, are critical for maintaining normal cutaneous hydration and barrier function (Weber et al, 2012). For this reason, new formulations containing ceramides (CeraVe) may also be particularly useful for skin conditions characterized by xerosis (dryness). Topical corticosteroids are potent anti-inflammatory agents available in a myriad of preparations and strengths. A detailed review of the use and dosing of topical corticosteroids is beyond the scope of this chapter, and the reader is directed to several excellent dermatology textbooks for more detail (Habif, 2004). It is important to recognize that even topical corticosteroids can include significant adverse effects, both from systemic absorption and also from the results of local application. Local effects include epidermal atrophy and the development of striae on the upper portion of the inner thigh,

dermal changes (telangiectasias, hypopigmentation), allergic reactions, and negative alterations in the usual course of skin infections and infestations (Burry, 1973). In most cases, atrophy is a reversible process that can be expected to resolve during the course of several months (Sneddon, 1976). Atrophy is particularly troublesome if corticosteroids are applied under the foreskin, which can serve as an occlusive “dressing” and can enhance penetration of the drug (Fig. 16-1) (Goldman and Kitzmiller, 1973).

A variety of physical modalities have also been applied to treat dermatologic problems, including ultraviolet light therapy, photodynamic therapy, laser therapy, and cryosurgery. Ultraviolet light therapy, with both broadband and narrow-band ultraviolet B (UVB), has been used to treat atopic dermatitis, psoriasis, seborrheic dermatitis, and vitiligo (Honigsmann and Schwarz, 2003). There are now several convenient single-wavelength UVB (308 nm) laser units with small spot sizes, which are particularly useful for treating vexing localized areas of genital psoriasis or vitiligo; such narrow spectrum machines are believed not to carry the risk of inducing the nonmelanoma skin cancer that is associated with broadband full-body light boxes. Psoralens, when combined with long-wave ultraviolet A radiation (psoralen ultraviolet A [PUVA] therapy), generate a phototoxic effect that is beneficial for treating psoriasis (Honigsmann, 2001; Stern, 2007), vitiligo (Honigsmann and Schwarz, 2003), atopic dermatitis (Morison, 1992), and lichen planus (Honigsmann and Schwarz, 2003). In general, the narrow-band UVB boxes and lasers have supplanted PUVA therapy, as the latter carries a substantial risk of squamous cell carcinoma (SCC) when performed throughout a prolonged period (Stern and PUVA Follow-Up Study, 2012). Photodynamic therapy involves the use of cytotoxic oxygen radicals generated from photoactivated molecules to achieve a therapeutic response (Tope and Shaffer, 2003; Braathen et al, 2007). Photodynamic therapy is a new arena of dermatologic therapy and holds promise for treating a variety of inflammatory, malignant, and infectious skin conditions. For example, photodynamic therapy is effective, both as monotherapy and in combination with cryosurgery, CO₂ laser ablation, and curettage, in the management of large or resistant condyloma acuminata or in genital warts occurring during pregnancy (Scheinfeld, 2013b). The downside to this promising modality is that there is not yet an

established optimum regimen for off-label use, including for genital warts. Laser and cryosurgery play a relatively small role in the management of genital lesions, although the CO₂ laser has been used effectively to manage genital condyloma acuminata, and cryosurgery may be useful for genital and suprapubic molluscum contagiosum.

ALLERGIC DERMATITIS

Allergic or “eczematous” dermatitis consists of a group of allergy-mediated processes leading to pruritic skin lesions (Box 16-1).

Atopic Dermatitis (Eczema)

Atopic dermatitis (AD) is a chronic relapsing dermatitis with a predilection for skin flexures that is associated with intense pruritus and damage to the epidermis (Williams, 2005). The characteristic lesions are erythematous papules and thin plaques with secondary excoriations (Fig. 16-2) (Kang et al, 2003). In

BOX 16-1 Differential Diagnosis of Allergic Dermatitis

- Eczema
- Allergic dermatitis

general, the lesions do not have a precise border as is common for papulosquamous disorders (Margolis, 2002). Although any age can be affected, 90% of AD patients manifest their condition before the age of 5 years (Rajka, 1989). AD is associated with susceptibility to a wide variety of substances that act as irritants (e.g., fragrances, preservatives, and various proteins). Patients suffering from AD also have a propensity to develop asthma and allergic rhinitis.

The genetic susceptibility to AD has been extensively explored. In a study of 372 AD patients, 73% had a positive family history for atopy. Likewise, twin concordance studies have demonstrated an AD risk of 0.86 for monozygotic twins compared to only 0.21 for dizygotic twins. These findings have spurred an intense search for genes involved in atopy and AD (Wollenberg and Bieber, 2000). Although no single gene has been found to be a unique marker for the disease, at least 11 genetic foci seem to be closely associated with AD (Kang et al, 2003; Ellinghaus et al, 2013). The single most important genetic defects confer an inability to synthesize functional filaggrin properly. This structural abnormality results in both a “leaky” epithelial barrier and chronic immune activation, which contribute to the pathophysiology of this common skin disease (Heimall and Spergel, 2012).

Intense pruritus is the hallmark of AD, and controlling the patient's urge to scratch is critical for successful treatment (Przybilla et al, 1994). Itching is often worse during evening hours and can be exacerbated by sweating, occlusive undergarments, or wool clothing (Kang et al, 2003). Scratching of lesions may contribute to the clinical complications of AD, including superinfection with *Staphylococcus aureus* species (Ogawa et al, 1994). There is growing evidence that bacterial toxins may serve as superantigens that drive an inflammatory cascade that sustains AD (Skov and Baadsgaard, 2000; Skov et al, 2000).

Clinically, there is no pathognomonic laboratory test, biopsy result, or single clinical feature that allows the definitive diagnosis of AD. The association with a personal or family history of atopy is a critical clue to the diagnosis (Kang et al, 2003). For patients presenting with genital findings, extragenital involvement is commonplace.

A variety of “trigger factors” have been implicated in the exacerbation of AD, including chemicals, detergents, and household dust mites. Removal of these factors from the environment may be beneficial on an individualized basis. Dust mite exposure, in particular, has received significant attention in the literature. Although several studies have demonstrated modest improvement in AD with mite reduction (Kubota et al, 1992; Tan et al, 1996), others report that reduction is associated with no significant clinical benefit (Colloff et al, 1989; Gutgesell et al, 2001).

Treatments for AD include gentle cleaning with nonalkali soaps or soap substitutes (e.g., Cetaphil, Aquanil) and the frequent use of emollients. Evaporation of liquid from the skin may trigger AD (Kang et al, 2003), so frequent bathing is not encouraged. Soaking may help during episodes of bacterial superinfection but should be discontinued after the infection has resolved (Margolis, 2002). Topical corticosteroids may be needed to control pruritus but should only be used for short courses with a rapid taper to avoid local complications of skin atrophy and dyschromia. Topical macrolide immunomodulatory agents such as tacrolimus and pimecrolimus have shown efficacy in the treatment of AD (Meagher et al, 2002; Nghiem et al, 2002; Luger and Paul, 2007; Leung et al, 2009), and these agents may decrease the need for corticosteroids during long-term therapy (Zuberbier et al, 2007). Antihistamines such as diphenhydramine or a variety of nonsedating agents, such as cetirizine, loratadine, and analogues of these, may be helpful in breaking the “itch-scratch cycle” in AD, particularly when administered before bedtime (Kang et al, 2003). Oral antistaphylococcal drugs have not been shown to significantly improve AD in a randomized, double-blind trial (Ewing et al, 1998). Systemic treatment with azathioprine, corticosteroids, cyclosporine, methotrexate, or mycophenolate mofetil may rarely be indicated for severe, widely disseminated cases (Cooper, 1993; Salek et al, 1993; Denby and Beck, 2012).

Contact Dermatitis

Contact dermatitis can be broken down into two distinct entities: irritant contact dermatitis (ICD) and allergic contact dermatitis (ACD). Although the mechanisms differ significantly, the clinical presentation of ICD and ACD may be similar. Most notably, the affected area is usually sharply limited to an area of skin exposure to true allergen or irritating chemical. The primary mode of treatment is to identify and reduce exposure to the offending agent.

ICD results from a direct cytotoxic effect of an irritant chemical touching the skin and is responsible for approximately 80% of contact dermatitis cases (Marks et al, 2002). Examples of offending agents include soaps, solvents, metal salts, and acid- or alkali-containing compounds. Occupational ICD is a serious public health problem and contributes to costs on the scale of \$1 billion annually in the United States (Cohen, 2000). The clinical manifestations of ICD depend on the identity of the irritating substance as well as the duration of contact, concentration, temperature, pH, and location of exposure. Acute ICD, such as might result from an occupational accident, generally peaks within minutes to hours after exposure and then begins to heal. Symptoms of burning, stinging, and soreness may be accompanied by erythema, edema, bullae, or frank necrosis in a sharply defined area corresponding to the exposed skin (Cohen and Bassiri-Tehrani, 2003). There are also a variety of subacute forms of ICD that result from repeated subthreshold skin insults. Pruritus is much more common in these more chronic conditions, and the skin lesions are not as well demarcated. The mainstay of treatment for ICD lies in avoiding skin contact with the causative irritants through the use of protective clothing, safe occupational practices, and the use of skin barrier preparations such as ointments, emollient creams, or protective foams. Some commercially available barrier products include Atopiclair, Biafine, EpiCeram, Mimyx, Neosalus Foam, and PruMyx (Berndt et al, 2000; Draelos, 2012).

In contrast, ACD represents a local type IV hypersensitivity reaction to a skin allergen to which an individual has been previously exposed and sensitized. The typical appearance is a well-demarcated pruritic eruption, which may manifest blistering or weeping in the acute phase or the development of scaly plaques more chronically (Mowad and Marks, 2003). In 2003 and 2009, the North American Contact Dermatitis Group (NACDG) reported a long list of common allergens implicated in ACD based on patch testing results (Zug et al, 2009). Similar lists that were produced subsequently contain the same set of allergens, with only a few exceptions. Patch testing is a simple technique of exposing an area of skin to a variety of potential allergens at a known concentration in a grid template (Fig. 16-3). Generally performed by dermatologists, patch testing can help to confirm both the diagnosis of ACD and the allergen involved. The most common sensitizing allergen identified by the NACDG was nickel sulfate (Zug et al, 2009), which is a common component of costume jewelry and belt buckles (Fig. 16-4). Although traditionally a cause of earlobe dermatitis from pierced earrings, nickel sensitivity may be a potential cause of genital ACD resulting from the increasing prevalence of genital piercing. Other important allergens include textile dyes, topical antibiotics, perfumes and other fragrance materials, formaldehyde-releasing preservatives, the latex in condoms, and topical corticosteroids. When ACD is suspected, one should always inquire about the use of over-the-counter products such as genital moisturizers, antiyeast and anti-itch preparations, and lubricants used during sexual intercourse. Oral antihistamines may be helpful for the symptomatic control of ACD in combination with the removal of the inciting allergen. Severe ACD should *not* be treated with a short course of systemic steroids, but rather with a 3-week tapering dose of prednisone.

Erythema Multiforme and Stevens-Johnson Syndrome

Erythema multiforme (EM) is a generalized skin disease that may involve the genitalia. EM can be subdivided into minor and major forms.

Figure 16-3. An example of patch testing with a positive response to nickel. (From Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003. p. 233.)

Figure 16-4. Contact dermatitis caused by a nickel allergy from a belt buckle. (From Habif TP. *Clinical dermatology*. Edinburgh: Mosby; 2004. p. 94.)

EM minor was first described in 1860 by an Austrian dermatologist, Ferdinand von Hebra ([von Hebra, 1860](#)). This condition is an acute, self-limited skin disease characterized by the abrupt onset of symmetrical fixed red papules that may evolve into target lesions ([Weston, 1996](#)). EM is a clinical rather than a histologic

Figure 16-5. Erythema multiforme (EM). A, Targetoid lesions of the hands and penis. B, Typical microscopic picture of EM with a normal stratum corneum, necrotic keratinocytes in the epidermis and a lymphoid infiltrate. (A, From Korting GW. *Practical dermatology of the genital region*. Philadelphia: Saunders; 1981. p. 16; B, from Elston DM, Furrer T. *Dermatopathology*. Edinburgh: Saunders; 2009. p. 147.)

diagnosis. Papules and target lesions are usually grouped and can be present anywhere on the body, including the genitalia ([Fig. 16-5A](#)). There is also a predilection for involvement of the oral mucous membranes, as well as the palms and soles.

The majority of cases of recurrent EM minor are precipitated by human herpesvirus 1 and 2 ([Schofield et al, 1993](#); [Nikkels and Pierard, 2002](#)), with herpetic lesions usually preceding the development of target lesions by 10 to 14 days ([Lemak et al, 1986](#)). Although continuous suppressive acyclovir may prevent EM episodes in patients with herpes infection ([Tatnall et al, 1995](#)), administration of the drug after development of target lesions is of no benefit ([Huff, 1988](#)). The natural history of EM minor is spontaneous resolution after several weeks without sequelae ([Schofield et al, 1993](#)), although recurrences are common ([Huff and Weston, 1989](#)). Oral antihistamines may provide symptomatic relief. For immunosuppressed patients, the time course of EM minor outbreaks may be longer and the frequency of recurrence may be greater ([Schofield et al, 1993](#)).

The major form of EM has been called Stevens-Johnson syndrome (SJS) in the past, although there remains some controversy as to whether EM major and SJS are distinct entities or are part of a spectrum of disease ([Bachot and Roujeau, 2003](#); [Williams and Conklin, 2005](#)). SJS is a much more serious illness than EM minor and it includes features similar to extensive skin burns ([Parrillo, 2007](#)). In its more severe forms, SJS may mimic life-threatening toxic epidermal necrolysis. Admission to the intensive care unit or burn unit may significantly reduce the morbidity and mortality of

Figure 16-6. Labial erosions in a case of Stevens-Johnson syndrome. (From Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003. p. 319.)

this condition (Wolf et al, 2005). Most patients with SJS exhibit a prodromal upper respiratory illness (fever, cough, rhinitis, sore throat, and headache), which progresses after 1 to 14 days to the abrupt development of red macules with blister formation and areas of epidermal necrosis. Genital involvement includes erythema and erosions of the labia (Fig. 16-6), penis, and perianal region.

A vast array of inciting factors has been implicated in the development of SJS, with drug exposures being the most commonly identified. Among the most common offending agents are non-steroidal anti-inflammatory agents, sulfonamides (particularly cotrimoxazole), tetracycline and doxycycline, penicillin and cephalosporins, and a wide range of anticonvulsants (Chan et al, 1990). In contrast to EM minor, there is rarely an association with an infectious agent (Weston, 2003). SJS generally presents a protracted course of 4 to 6 weeks and may include a mortality rate approaching 30%. Severe scarring of denuded skin may result in a range of complications including joint contractures, labial synechia, vaginal stenosis, urethral meatal stenosis, and anal strictures (Brice et al, 1990; Weston, 2003). Treatment involves immediate removal of the offending drug and supportive care similar to the management of severe burns. There is currently no strong evidence for any specific medical therapy for SJS (Weston, 2003), and the role of systemic corticosteroids in treating SJS remains controversial (Rasmussen, 1976; Tripathi et al, 2000; Weston, 2003). Newer modalities anecdotally reported to act as effective interventions include cyclosporine (3 to 5 mg/kg/day), tumor necrosis factor (TNF)- α inhibitors, plasmapheresis, and, especially noted, intravenous immunoglobulin (Mockenhaupt, 2011; Worswick and Cotliar, 2011). Care of the SJS patient is best accomplished via a multispecialty team approach.

PAPULOSQUAMOUS DISORDERS

Papulosquamous disorders are a disparate group of diseases that share a common primary lesion: scaly papules and plaques (Box 16-2).

Psoriasis

Psoriasis is a common disease affecting up to 2% of the population (Christophers, 2001; Nestle et al, 2009). For patients with a

From Margolis DJ. Cutaneous disease of the male external genitalia. In: Walsh PC, editor. *Campbell's urology*. Philadelphia: Saunders; 2002.

predisposition, which is likely polygenic in nature, triggering factors such as trauma, infection, psychological stress, or new medications can elicit a flare in the psoriatic phenotype. One third of affected patients have a family history of psoriasis (Melski and Stern, 1981; Hensler and Christophers, 1985; Margolis, 2002).

The characteristic lesion is a sharply demarcated erythematous plaque with silvery-white scales (van de Kerkhof, 2003). Its pattern can be limited to the elbows or knees or can be distributed on the entire surface of the skin. Although psoriasis can appear at any age, two peaks of onset have been identified: 20 to 30 and 50 to 60 years of age. Patients complain of a significant impairment in their quality of life as a result of pruritus and bleeding, as well as the cosmetic and psychosocial impact of these visible plaques.

Psoriatic involvement of the genitalia is relatively common although it is usually within the context of a generalized cutaneous disorder. Patients may present with concerns for malignancy or sexually transmitted disease (STD) when psoriatic lesions are present on the genitalia. Genital psoriasis leads to impaired self-esteem and reduced sexual self-image, thereby interfering with normal intimate relationships, particularly in women (Magin et al, 2010; Meeuwis et al, 2011). The presence of characteristic lesions on the elbows, knees, buttocks, nails, scalp, and umbilicus may help direct the diagnosis (Fig. 16-7A) (Margolis, 2002). When lesions are present in the inguinal folds and intergluteal cleft, scaling may be absent (so-called inverse psoriasis) (Goldman, 2000). When evaluating nonscaling erythematous plaques in the inguinal folds, the diagnosis of fungal involvement (i.e., tinea or *Candida*) should be considered and ruled out by KOH preparation or fungal culture. In circumcised men, psoriatic plaques are often present on the glans and corona whereas in uncircumcised men, lesions are commonly hidden under the preputial skin (Buechner, 2002). In some cases, however, psoriasis involves the entire penis and scrotum (Fig. 16-8).

Psoriasis is a chronic disease with a relapsing and remitting course. A variety of topical and systemic therapies have been developed and are applied to this difficult problem. Despite the variety of therapy, however, as many as 40% of psoriasis sufferers express frustration at the ineffectiveness of current treatments (Krueger et al, 2001). For genital psoriasis, the mainstay of therapy is the use of low-potency topical corticosteroid creams for short courses (Kalb et al, 2009). Examples include a preparation of 3% liquor carbonis detergens (a tar derivative) in 1% hydrocortisone cream or hydrocortisone butyrate 0.1% (Fisher and Margesson, 1998). These preparations should not be used for more than 2 weeks continuously on thin genital skin or in areas occluded by skin folds (Margolis, 2002). Other topical therapies for psoriasis include vitamin D₃ analogues (calcitriol, calcipotriene), topical

calcineurin inhibitors (pimecrolimus cream and tacrolimus ointment), and low-potency retinoids, although these agents are sometimes too irritating or not sufficiently effective. Photochemotherapy combining an ingested psoralen with ultraviolet radiation (PUVA) has been used extensively to treat psoriasis (Stern, 2007). However, a dose-dependent increase in the risk of genital SCC has been

associated with high-dose PUVA therapy for psoriasis elsewhere on the body (Stern, 1990; Stern et al, 2002). Genital shielding during PUVA therapy is strongly recommended; therefore this modality is contraindicated for treating psoriatic lesions localized to genital skin. For patients with extensive psoriasis, systemic therapy with methotrexate, cyclosporine, retinoids, or one of the approved TNF- α inhibitors (adalimumab, etanercept) or IL12/23 inhibitors (ustekinumab) may be appropriate. The 308-nm excimer laser (Gerber et al, 2003) is now approved for psoriasis treatment. Experimental therapies that have shown promise in treating psoriasis include vitamin D receptor ligands (Bos and Spuls, 2008) and antibodies or antisense oligonucleotides against T-lymphocyte surface molecules (Gottlieb et al, 2000b), TNF (Chaudhari et al, 2001; Bos and Spuls, 2008), or intracellular adhesion molecules (Gottlieb et al, 2000a).

Reactive Arthritis (Formerly Reiter Syndrome)

Reactive arthritis (formerly Reiter syndrome) is composed of urethritis, arthritis, ocular findings, oral ulcers, and skin lesions. Only about one third of all patients with this disorder demonstrate all of the manifestations. The skin findings, particularly when present on the genitalia, may be mistaken for psoriatic lesions (Fig. 16-9). Reactive arthritis is more common in men than in women and is rarely diagnosed in children. Reactive arthritis is generally preceded by an episode of either urethritis (*Chlamydia*, *Gonococcus*) or gastrointestinal infection (*Yersinia*, *Salmonella*, *Shigella*, *Campylobacter*, *Neisseria* or *Ureaplasma* species) and is more common in human immunodeficiency virus (HIV)-positive patients (Rahman et al, 1992; Margolis, 2002; Wu and Schwartz,

Figure 16-7. Psoriasis. A, Silver scales on an erythematous base. B, Alternating neutrophils and parakeratosis in the stratum corneum of plaque psoriasis (sandwich sign). (A, From Callen JP, Greer DE, Hood AF, et al. Color atlas of dermatology. Philadelphia: Saunders; 1993. p. 320; B, from Elston DM, Ferringer T. Dermatopathology. Edinburgh: Saunders; 2009. p. 152.)

Figure 16-8. Psoriasis involving the entire penis and scrotum. (From Bologna JL, Jorizzo JL, Rapini RP. Dermatology. Edinburgh: Mosby; 2003. p. 130.)

Figure 16-9. Comparison of psoriasis (A) and reactive arthritis (B) (balanitis circinata) involving the glans penis. Note the highly characteristic coalescence of lesions in this case of reactive arthritis forming a wavy pattern (arrow). (From Habib TP. Clinical dermatology. Edinburgh: Mosby; 2004. p. 217.)

Figure 16-10. Erosive psoriaform lesions of the glans penis (reactive arthritis; balanitis circinata) may also lack the wavy pattern, making them difficult to differentiate from genital psoriasis. (From Callen JP, Greer DE, Hood AF, et al. *Color atlas of dermatology*. Philadelphia: Saunders; 1993. p. 160.)

2008). There is a strong genetic association with the human leukocyte antigen (HLA)-B27 haplotype. Whether or not cross-reactivity between bacterial antigens and HLA-B27 leads to autoimmunity in reactive arthritis remains controversial (Ringrose, 1999; Yu and Kuipers, 2003).

Conjunctivitis is the most common ocular manifestation, although iritis, uveitis, glaucoma, and keratitis may occur. Polyarthritides and sacroiliitis are the most common orthopedic complaints and may lead to chronic disability in a small minority of cases (van de Kerkhof, 2003). Scaly, erythematous psoriaform skin lesions appearing on the penis are referred to as *balanitis circinata* (Fig. 16-10), and similar lesions on the soles are referred to as *keratoderma blennorrhagicum*. These lesions may be difficult to distinguish from psoriasis, and histologic analysis of biopsy specimens cannot consistently differentiate the two conditions (Margolis, 2002). The course of reactive arthritis involving the genitalia is usually self-limited, lasting a few weeks to months. Lesions may respond to low-potency topical corticosteroids, and systemic therapy is rarely required. Lesions on soles, however, are more persistent; these respond well to the application of potent topical retinoids such as tazarotene (Lewis et al, 2000).

Lichen Planus

Lichen planus (LP), the prototype of the lichenoid dermatoses, is an idiopathic inflammatory disease of the skin and mucous membranes. The characteristic “lichenoid tissue reaction” is characterized by epidermal basal cell damage that is associated with a massive infiltration of mononuclear cells in the papillary dermis (Shiohara and Kano, 2003). Cutaneous LP may affect up to 1% of the adult population (Boyd and Neldner, 1991) and oral lesions may be present in as many as 4% (Scully et al, 1998). The pathogenesis of LP appears related to an autoimmune reaction against basal keratinocytes, which express altered self-antigens on their surfaces (Morhenn, 1986).

The primary lesion of LP is a small, polygonal-shaped, violaceous, flat-topped papule. These lesions may be widely separated or may coalesce into larger plaques that may ulcerate, particularly on mucosal surfaces. LP commonly involves the flexor surfaces of the extremities, the trunk, the lumbosacral area, the oral mucosa, and the glans penis (Margolis, 2002). On the male genitalia, the clinical presentation of LP can be quite variable and includes isolated or grouped papules, a white reticular pattern, or an annular (ringlike) arrangement with or without ulceration (Fig. 16-11). In some cases, the lesions appear to form linear patterns related to skin trauma (the so-called Koebner phenomenon, which is also seen with psoriasis). On the female genitalia, painful erosion of erythematous plaques is common; in long-standing LP of the vulva, some areas of hyperhydrated hyperkeratosis (manifesting as white plaques) may surround shallow erosions. In women, more than in men, concomitant oral LP may be found on the buccal mucosa or tongue (Santegoets et al, 2010). The differential diagnosis of LP includes invasive and in situ SCC, Zoon balanitis, psoriasis, secondary syphilis, herpes and extramammary Paget disease, and lupus erythematosus. Biopsy may be necessary to establish the diagnosis, particularly when the lesions are small, multiple, and ulcerated (Shiohara and Kano, 2003). Lichenoid reactions can also occur in response to ingested drugs and contact allergens, and a careful search for potential offending agents is appropriate.

The natural history of LP is benign and the spontaneous resolution of cutaneous lesions has been observed in up to two thirds of cases after 1 year (Shiohara and Kano, 2003), although the oral form may persist significantly longer, and isolated cases of SCC arising within chronic genital LP have been reported (Mignogna et al, 2000). Although bothersome pruritus (more often in men) or pain/burning (more often in women) is common with LP, asymptomatic lesions on the genitalia do not require treatment. The primary modality of treatment for symptomatic genital LP is the application of an ultrapotent topical corticosteroid (such as clobetasol 0.05% or halobetasol 0.05%). There is also a role for topical calcineurin inhibitors (pimecrolimus cream, tacrolimus ointment) in the management of genital LP (Luger and Paul, 2007). For severe cases, systemic corticosteroids (15 to 20 mg/day; 2- to 6-week course) (Boyd and Neldner, 1991) have been shown to shorten the time course to clearance of LP lesions from 29 weeks to 18 weeks (Cribier et al, 1998). Other systemic therapies for severe LP include cyclosporine, tacrolimus, griseofulvin, metronidazole, and acitretin (Ho et al, 1990; Boyd and Neldner, 1991; Cribier et al, 1998; Buyuk and Kavala, 2000; Madan and Griffiths, 2007), although randomized trials demonstrating efficacy are generally lacking. In fact, as pointed out in an exhaustive meta-analysis, there is no overwhelmingly reliable evidence for the efficacy of any single treatment for erosive mucosal LP, including application of an ultrapotent topical steroid, which is the widely accepted first-line therapy (Cheng et al, 2012).

Lichen Nitidus

Lichen nitidus (LN) is an unusual inflammatory eruption characterized by tiny, discrete, flesh-colored papules arranged in large clusters. Although there is some debate as to whether LN may represent a variant of LP (Aram, 1988), the two entities are histologically distinct. LN has a dense, well-circumscribed, lymphohistiocytic infiltrate that is closely apposed to the epidermis (Shiohara and Kano, 2003). Commonly involved sites include the flexor aspects of the upper extremities, the genitalia, the trunk, and the dorsal aspects of the hands. Nail involvement is common. Similar to LP, the natural history of LN is one of spontaneous resolution, with the majority of patients (69%) manifesting the disease for less than 1 year (Lapins et al, 1978). Patients should be reassured that these genital lesions are not infectious and should resolve with time. For symptomatic pruritus, genital lesions usually respond to mid- to low-potency topical corticosteroids and oral antihistamines (Shiohara and Kano, 2003).

Figure 16-11. Lichen planus (LP). Various presentations of LP on the male genitalia. A and B, Both individual and grouped purple papules on the penile shaft, some oriented in a linear pattern. C, A white reticular pattern sometimes seen in LP. D, An annular (ringlike) arrangement with a shiny surface. E, Histologically, LP is characterized by destruction of the basal layer, a sawtooth rete ridge pattern, the presence of Civatte bodies and dermal melanocytes, and the absence of parakeratosis or eosinophils. (A, From Korting GW. *Practical dermatology of the genital region*. Philadelphia: Saunders; 1981. p. 29; B, C, and D, from du Vivier A. *Atlas of clinical dermatology*. London: Churchill Livingstone; 2002. p. 100; E, from Elston DM, Ferringer T. *Dermatopathology*. Edinburgh: Saunders; 2009. p. 137.)

Lichen Sclerosus

Lichen sclerosus et atrophicus (LS) is a chronic inflammatory disease of unknown etiology with a predilection for the external genitalia. LS is 6 to 10 times more prevalent in women than in men, generally presenting either around the time of menopause or in the prepubertal years (Wojnarowska and Cooper, 2003). It tends to affect older men (>60 years of age) (Ledwig and Weigand, 1989) and can be associated with pain during voiding or erection (Margolis, 2002). There is a strong familial predisposition for this disorder, suggesting a genetic contribution (Sherman et al, 2010). For patients with genital LS, 15% to 20% experience extragenital disease (Powell and Wojnarowska, 1999). LS is ultimately a scarring disorder characterized by tissue pallor, loss of architecture resulting from fibrosis, and hyperkeratosis (Fig. 16-12). Some cases of LS may demonstrate prominent purpura and fissuring; the former may be so severe as to obscure the typical “white” color of the disease. The

glans penis and foreskin are usually affected, and the perianal involvement common in women is usually absent. Preputial scarring from LS can lead to phimosis, and circumcision is usually curative, although recurrence in the circumcision scar may occur. The late stage of this disease is called *balanitis xerotica obliterans*, which can involve the penile urethra and result in troublesome urethral strictures. In women, the disease can eventually lead to vulvar adhesions, labial fusion, clitoral phimosis, and vaginal obstruction. LS can also be the cause of considerable genital itching, burning, pain, and dyspareunia in women.

Despite the similarities in name, LS shares little in common with LP and LN other than pruritus and a predilection for the genital region. Another critical distinction is that LS has been associated with SCC of the penis and vulva, particularly those variants not associated with human papillomavirus (HPV), and LS may represent a premalignant condition (Velazquez and Cubilla, 2003; Bleeker et al, 2009; van de Nieuwenhof et al, 2011).

Figure 16-12. A to C, Lichen sclerosus et atrophicus (balanitis xerotica obliterans) of the penis. Note the erythematous and white plaques involving the penile shaft, preputial skin, and glans. (A, From Callen JP, Greer DE, Hood AF, et al. *Color atlas of dermatology*. Philadelphia: Saunders; 1993. p. 327; B, from du Vivier A. *Atlas of clinical dermatology*. London: Churchill Livingstone; 2002. p. 716; C, from Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003. p. 1101.)

LS includes specific histologic features, including basal cell vacuolation, epidermal atrophy, marked dermal edema, collagen homogenization, focal perivascular infiltrate of the papillary dermis, and plugging of the ostia of follicular and eccrine structures (Margolis, 2002). Biopsy is worthwhile both to confirm the diagnosis and to exclude malignant change (Powell and Wojnarowska, 1999). It has been suggested that the expression of selected cellular markers (such as p53, survivin, telomerase, Ki-67, and cyclin D1) can help distinguish between indolent LS and LS with true malignant potential (Carlson et al, 2013). In the future, biopsy specimens may routinely be investigated for these (and other) protein markers to determine prognosis.

From a management standpoint, long-term follow-up of patients with LS is important because of the association with SCC. The application of potent topical steroids (such as clobetasol propionate 0.05% or halobetasol 0.05%) for long courses (3 months) is well established as a treatment for LS in women, and may both improve symptoms and reverse the disease process (Dalziel et al, 1991). This regimen is contrary to the usual policy of avoiding long courses of steroid application to genital skin. The efficacy of similar approaches has not been definitively confirmed in adult men, although benefits have been demonstrated in the pediatric age group (Kiss et al, 2001). A European, multicenter, phase II trial also supported the safety and efficacy of topical tacrolimus in the treatment of long-standing LS (Hengge et al, 2006). The application of topical and administration of systemic retinoids, as well as photodynamic therapy, may be therapeutic options in rare cases refractory to standard therapeutic interventions. Because of a high rate of recurrence (40% to 50%) after seemingly successful initial therapy, some experts suggest the routine use of proactive (prophylactic) maintenance therapy with either midpotency topical steroids (such as mometasone furoate 0.1%) or topical calcineurin inhibitors (Virgili et al, 2013).

Fixed Drug Eruption

A fixed drug eruption occurs in response to oral medications, usually 1 to 2 weeks after the first exposure, and commonly involves the lips, face, hands, feet, and genitalia, particularly the glans penis (Fig. 16-13). After subsequent re-exposure to the drug, the reaction presents in the exact same location, usually within 24 hours (hence the term “fixed”). The most common medications causing this reaction are sulfonamides, nonsteroidal anti-inflammatory agents, barbiturates, tetracyclines, carbamazepine, phenolphthalein, oral contraceptives, and salicylates (Kauppinen and Stubb, 1985; Stubb et al, 1989; Thankappan and Zachariah, 1991). There have been isolated reports of fixed drug eruption associated with urologic drugs, such as finasteride, tadalafil, and fluconazole (administered for vulvovaginal candidiasis).

When present on the penile shaft or glans, these lesions are usually solitary, violaceous-colored, inflammatory plaques, which may become erosive and painful (Margolis, 2002). On the genitalia, the differential diagnosis includes herpes simplex infection or an insect bite. Removing the offending agent usually results in resolution of the lesion, although a postinflammatory brown pigmentation may remain. There should be no long-lasting residual functional defect from this process.

Seborrheic Dermatitis

Seborrheic dermatitis (SD) is a common skin disease characterized by the presence of sharply demarcated pink-yellow to red-brown plaques covered with an adherent flaky scale. It shares a variety of features in common with eczematous dermatitis and could easily be grouped in that category. Common dandruff is a mild form of SD localized to the scalp. It has a predilection for areas rich in sebaceous glands and is generally present only during the

Figure 16-13. Fixed drug eruptions. A to C, Involvement of the penis. D, Histologic features include a normal stratum corneum with chronic changes in the superficial dermis including an eosinophilic infiltrate. (A, From Callen JP, Greer DE, Hood AF, et al. *Color atlas of dermatology*. Philadelphia: Saunders; 1993. p. 160; B, from Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003. p. 345; C, from Habif TP. *Clinical dermatology*. Edinburgh: Mosby; 2004. p. 492; D, from Elston DM, Ferringer T. *Dermatopathology*. Edinburgh: Saunders; 2009. p. 149.)

first few months of life or postpuberty, when sebaceous glands are active. Commonly affected areas include the scalp, eyebrows, nasolabial folds, ears, and chest, although the anus, glans penis, and pubic areas may also be involved (Margolis, 2002). Circumcision may be somewhat protective against the development of SD. In one study of 357 patients, the risk of developing penile SD was 2.5 times greater in the uncircumcised state (Mallon et al, 2000).

Adult SD includes a chronic relapsing course (Webster, 1991). This condition is particularly common in patients with Parkinson disease, and up to 83% of acquired immunodeficiency syndrome (AIDS) patients may manifest SD (Froschl et al, 1990; Gupta and Bluhm, 2004). Particularly in immunosuppressed individuals, SD may involve a significant proportion of the body surface area. Extensive and/or severe SD should raise concerns for possible underlying HIV infection (Fritsch and Reider, 2003). SD may be pruritic, and differentiation from psoriasis may occasionally be problematic. Unlike psoriasis, however, SD rarely involves the nails and tends to have a thinner associated scale.

Controversy concerning the etiology of SD revolves around a possible autoimmune response to a component of normal skin flora, the yeast *Malassezia furfur* (*Pityrosporum ovale*). Although *M. furfur* can be isolated from the lesions of SD, the number of organisms is only about twice that observed in normal control skin (Nenoff et al, 2001). Likewise, severely SD-affected HIV patients do not harbor more organisms than HIV patients who do not manifest

SD (Pechere et al, 1999). Another factor potentially linked to SD is an elevated level of triglycerides and cholesterol at the skin surface (Fritsch and Reider, 2003).

Creams or foams containing topical antifungals (i.e., ketoconazole) are the mainstay of SD treatment on the body and include a 75% to 90% response rate (Faergemann, 2000; Fritsch and Reider, 2003; Elewski et al, 2007). For hair-bearing areas, "antidandruff" shampoos containing zinc, salicylic acid, selenium sulfide, tar, ciclopirox olamine, or 1% to 2% ketoconazole are effective (Margolis, 2002; Squire and Goode, 2002). Because of the chronic and relapsing nature of SD, treatment often must be repetitive and prolonged. Low-potency topical corticosteroids may play a role during the initial treatment of severe cases, but they should not be the primary mode of treatment for this condition because of the potential for local steroid side effects.

VESICOBULLOUS DISORDERS

Vesicobullous disorders are uncommon conditions often characterized by autoimmune damage to the epidermis or basement membrane (Box 16-3). Although intact blisters may be found on the groin and suprapubic skin per se, the rupture of vesicles and bullae on the genitalia may only leave behind residual erosions (Margolis, 2002).

BOX 16-3 Differential Diagnosis of Vesicobullous Disorders

Bullous pemphigoid
 Pemphigus vulgaris
 Pemphigus foliaceus
 Zoon balanitis
 Behçet syndrome
 Contact dermatitis
 Dermatitis herpetiformis
 Porphyria cutanea tarda
 Herpes zoster
 Herpes simplex
 Lymphangioma circumscriptum
 Impetigo
 Fixed drug eruption
 Factitial
 Innocent trauma
 Benign familial pemphigoid (Hailey-Hailey disease)

Figure 16-14. Characteristic painful oral mucosal erosions in pemphigus vulgaris. (From Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003. p. 455.)

Pemphigus Vulgaris

Pemphigus is a family of autoimmune blistering diseases characterized by intraepidermal blisters resulting from the loss of keratinocyte cell-cell adhesion (Martel and Joly, 2001). These blisters are located in the deep epidermis close to the basal cell layer. The proposed immunopathology includes the development of autoantibodies directed against keratinocyte cell surface markers and desmosomes (Amagai et al, 1996; Zhou et al, 1997; Joly et al, 2000).

Almost all pemphigus patients will exhibit painful oral mucosal erosions and more than half will experience cutaneous blisters that may involve the genitalia. Characteristic oral lesions are therefore an important clue to the diagnosis (Fig. 16-14). The

cutaneous blisters are thin-walled and easily broken to leave behind a painful erosion. The loss of epidermal cohesion seen in pemphigus leads to the characteristic Asboe-Hansen sign: spreading of fluid under the adjacent normal-appearing skin away from the direction of pressure on the blister (Amagai, 2003). **In severe cases without appropriate treatment, pemphigus may lead to fatal septicemia as a result of the loss of the epidermal barrier function of large areas of affected skin.** Treatment for pemphigus traditionally depends on systemic corticosteroids, although minimization of steroid dose is an important goal to limit side effects. The addition of immunosuppressive agents such as azathioprine, cyclophosphamide, and mycophenolate mofetil may be beneficial because of their corticosteroid-sparing effect (Amagai, 2003). In recent years, the use of rituximab as monotherapy (1000 mg administered intravenously on days 1 and 15; repeated in 1 month if necessary) has gained considerable support because of high efficacy rates (>70% with a single cycle) and low relapse rates (22% at 8 to 12 months) (Leshem et al, 2013). The infusion of intravenous immunoglobulin may also prove effective and presents an inherent advantage of lowering infectious complication rates (Ruocco et al, 2013). The management of pemphigus is difficult and should always be performed in concert with a dermatologist or a rheumatologist who has experience with this disease.

Bullous Pemphigoid

Bullous pemphigoid (BP) is a subepidermal blistering disease that is more common in men and generally afflicts patients older than 60 years of age (Rzany and Weller, 2001). There is enrichment for specific HLA class II alleles in BP patients as compared to normal controls (Delgado et al, 1996), supporting an autoimmune mechanism of pathogenesis. In BP, autoantibodies against specific proteins involved in cell-cell adhesion (BP180, BP230) are present. These proteins are components of hemidesmosomes, which are structures that mediate epidermal-stromal adhesion. Binding of autoantibodies to these structures leads to complement activation and a cascade of events resulting in tissue damage, epidermal-dermal separation, and blister formation (Kitajima et al, 1994; Lin et al, 1997).

The clinical presentation of BP can be highly variable. It generally begins with a nonbullous phase characterized by severe itching and nonspecific skin findings. As the disease moves into the bullous phase, vesicles and blisters appear on normal skin or, most characteristically, on areas containing confluent erythematous plaques. The blisters are tense, tend to form on flexor surfaces, and may involve the inner thighs and genitalia (Fig. 16-15A). Mucous membranes may also be involved, although this is less common than in pemphigus. **The diagnosis is made by a combination of clinical, histologic, and, often most importantly, immunohistochemical features such as the deposition of IgG antibodies along the basement membrane (Fig. 16-15B) (De Jong et al, 1996).** Treatment of BP in the United States is traditionally similar to that described for pemphigus, with systemic corticosteroids and various immunosuppressives playing primary roles (Kirtschig and Khumalo, 2004). However, based on the results of several randomized comparative studies, the Europeans favor the use of superpotent topical steroids for the management even of extensive pemphigoid (Joly et al, 2002, 2009). Certainly, treatment of limited-extent pemphigoid should rely heavily on topical, rather than systemic, corticosteroids. For treatment-resistant cases, oral methotrexate, intravenous immunoglobulin, plasmapheresis, or intravenous rituximab may be beneficial (Hatano et al, 2003; Lee et al, 2003; Ruetter and Luger, 2004; Wetter et al, 2005; Shetty and Ahmed, 2013).

Dermatitis Herpetiformis and Linear IgA Bullous Dermatitis

Both of these entities are blistering autoimmune skin diseases associated with the deposition of IgA antibodies at the basement membrane.

Figure 16-15. Bullous pemphigoid (BP). A, Involvement of the inner thighs. Note the confluent plaques and tense blisters in the inguinal area. B, Direct immunofluorescence of BP showing deposition of autoantibodies (IgG) at the dermoepidermal junction. (A, From Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003. p. 465); B, from Elston DM, Ferringer T. *Dermatopathology*. Edinburgh: Saunders; 2009. p. 169.)

Figure 16-16. Linear IgA bullous dermatosis. A, Direct immunofluorescence showing linear deposition of IgA along the dermoepidermal junction. B, Typical circumferential and linear patterns of vesicles. (A, From Elston DM, Ferringer T. *Dermatopathology*. Edinburgh: Saunders; 2009. p. 170; B, from Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003. p. 485.)

Dermatitis herpetiformis is a cutaneous manifestation of celiac disease and is generally associated with gluten sensitivity (Karpati, 2004). It is most common in people of northern European origin. There is a close association of dermatitis herpetiformis with certain HLA class II DQ2 alleles (DQA1*0501, DQB1*02) (Reunala, 1998). Pruritic plaques, papules, and vesicles in a symmetrical distribution characterize dermatitis herpetiformis. These vesicles may form “herpetiform” groups on an erythematous base. Patients may also complain of pain and burning over the lesions. Diagnosis can be confirmed by biopsy and direct immunofluorescence, which shows a granular pattern of IgA deposition at the basement membrane. Treatment includes the use of dapsone and a strict gluten-restricted diet (Frodin et al, 1981; Andersson and Mobacken, 1992).

Linear IgA bullous dermatosis (LABD), in contrast, is not associated with celiac disease. As the name implies, a linear pattern of antibody deposition at the basement membrane is found on immunohistochemistry in LABD (Fig. 16-16). Characteristic clinical features include vesicles and bullae arranged in a combination of circumferential and linear orientations. Treatment with either sulfapyridine or dapsone is usually effective in controlling LABD, and long-term spontaneous remission rates of 30% to 60% have been described (Wojnarowska et al, 1988). In contrast to both

pemphigus and BP, neither dermatitis herpetiformis nor LABD commonly affects genital or perigenital skin.

Hailey-Hailey Disease

Hailey-Hailey disease is an autosomal dominant blistering dermatosis related to various mutations in the ATP2C1 gene. The ATP2C1 gene encodes the protein product hSPCA1, which is a $\text{Ca}^{2+}/\text{Mn}^{2+}$ transporter. This protein is responsible for calcium homeostasis in the Golgi apparatus required for the post-translational processing of junctional proteins involved in proper epidermal cell-cell adhesion. Hailey-Hailey disease usually develops within the second or third decade of life (Burge, 1992). It has a characteristic predilection for the intertriginous areas including the neck, axillae, groin, and perianal region (Fig. 16-17). In women, disease in the inframammary folds is common although vulvar disease is unusual (Wieselthier and Pincus, 1993). Symptoms include an unfortunate combination of pruritus, pain, and a foul odor. As heat and sweating exacerbate the condition, Hailey-Hailey disease tends to worsen dramatically during the summer months (Burge, 1992). Skin findings include confluent areas of fragile vesicles and blisters, which form as a result of the

aberrant keratinocyte cell adhesion. Lesions may be confined to the axilla or groin, and superinfection with yeast, bacteria or herpes simplex virus may compound the problem. Histologic examination may be helpful in differentiating Hailey-Hailey disease from impetigo, pemphigus, intertrigo, and Darier disease (Margolis, 2002). Treatment includes wearing lightweight, breathable clothing to avoid friction and sweating. Lesions may respond to topical or intralesional corticosteroids, with the caveats mentioned previously about the use of these agents on intertriginous skin. For disease that is resistant to medical therapy, wide excision and skin grafting have been effective, as have local ablative techniques such as dermabrasion, photodynamic therapy, and CO₂ or erbium-YAG laser vaporization (Hamm et al, 1994; Christian and Moy, 1999; Hohl et al, 2003). An innovative approach to this disorder is to inject infected areas with botulinum toxin type A; this therapy greatly reduces sweating and thereby reduces disease severity (Bessa et al, 2010).

NONINFECTIOUS ULCERS

Genital ulcers can be a result of both infectious and noninfectious causes (Box 16-4).

Aphthous Ulcers and Behçet Disease

Aphthous ulcers are small, painful erosions that commonly involve the oral cavity (so-called canker sores) but they can occasionally be present on the genitalia. When oral and genital aphthous ulcers coexist, the clinician should seriously consider the diagnosis of Behçet disease (BD). BD is a generalized relapsing and remitting ulcerative mucocutaneous disease that likely involves a genetic predisposition and an autoimmune mode of pathogenesis (Sakane, 1997; Mendes et al, 2009). Although many genetic loci have been implicated, perhaps the strongest association is with HLA B51. Oxidative stress related to the overproduction of superoxide radicals by neutrophils has also been implicated in the development of this condition (Freitas et al, 1998; Najim et al, 2007). However, a large number of other etiopathogenetic mechanisms have been proposed and supported by experimental findings (such as IL-10 gene mutations) (Remmers et al, 2010). The notable variability in efficacy for any of the therapeutic interventions enumerated later suggests that pathways of inflammation in BD are unlikely to be uniform. BD has a high prevalence in Turkey (80 per 100,000), Israel (15 per 100,000), and Japan (10 to 12 per 100,000), but it is quite rare in the United States (0.12 to 5.0 per 100,000) (Arbesfeld and Kurban, 1988; Calamia et al, 2009). Affected individuals may also suffer from epididymitis, thrombophlebitis, aneurysms (particularly of the pulmonary artery), and gastrointestinal, neurologic, and arthritic problems (Koc et al, 1992; Tuzun et al, 1997; Cetinel et al, 1998; Krause et al, 1999; Aykutlu et al, 2002; Margolis, 2002). BD occurs with roughly similar frequency among males and females, although men typically experience a more severe course.

Mucocutaneous lesions of the oral cavity and genitalia (Fig. 16-18) and ocular involvement (uveitis) form a triad of clinical features in BD. The genital lesions are larger and generally more painful than the oral lesions. Optic involvement occurs in 90% of cases and may lead to blindness (Moschella, 2003). The Behçet International Study Group has defined the diagnosis as recurrent oral ulceration plus any two of the following: recurrent genital ulceration, eye lesions, cutaneous lesions, and skin sensitivity to needle puncture (pathergy test) (Criteria for diagnosis of Behçet's disease. International Study Group for Behçet's Disease, 1990). Other causes for genital ulceration, however, including simple aphthous ulcers, primary syphilis, herpes simplex, and chancroid, must be considered before a diagnosis of BD is made (Margolis, 2002). While using these accepted criteria, it should be noted that oral ulceration is the most sensitive lesion and genital ulceration is the most specific lesion. The latter therefore is the most clinically useful

Figure 16-18. Scrotal (A), perianal (B), and oral (C) ulcers seen in Behçet disease. (A, From du Vivier A. *Atlas of clinical dermatology*. London: Churchill Livingstone; 2002. p. 713; B and C, from Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003. p. 419.)

lesion in diagnosing BD according to this schema. Nonetheless the diagnosis of BD depends exclusively on the aggregate clinical findings, as there are no specific laboratory, radiologic, genetic, or histologic findings that conclusively confirm this diagnosis (Hatemi et al, 2013).

The clinical course of BD is protean, and randomized controlled trials in support of specific therapy are currently limited (Kaklamani and Kaklamanis, 2001). A wide range of topical and systemic agents has been applied to treat BD with variable success, including corticosteroids, dapsone, colchicine, immunosuppressants, 5-aminosalicylic acid (5-ASA) derivatives, cyclosporine A, and TNF- α inhibitors (especially infliximab and adalimumab) (Moschella, 2003; Kose et al, 2009). It has become clear that earlier and more aggressive treatment of BD-associated significant organ involvement with immunosuppressives and biologics has improved the overall outcome. Rheumatologic consultation is advised when this diagnosis is suspected.

Pyoderma Gangrenosum

Pyoderma gangrenosum (PG) is a rare ulcerative skin disease associated with systemic illnesses including inflammatory bowel disease, arthritis, collagen vascular disease, chronic active hepatitis, HIV infection, and myeloproliferative disorders (Moschella, 2003). It most commonly affects women between the second and fifth decade of life and likely has an autoimmune pathogenesis given its association with other autoimmune diseases. Between 20% and 50% of cases, however, are idiopathic. The annual incidence of PG in the United States is about 1 case per 100,000 individuals.

The classic morphologic presentation of PG is painful cutaneous and mucous membrane ulceration, often with extensive loss of tissue and a purulent base (Fig. 16-19). Although unusual, PG can

involve the penis, scrotum, vulva, and peristomal sites (Cairns et al, 1994). As was the case in BD, no specific diagnostic laboratory test or histopathologic feature is pathognomonic for PG, although a history of an underlying systemic disease may raise suspicion. Aside from ulcerative STDs, the differential diagnosis of penile PG includes calciphylaxis, BD, necrotizing fasciitis, cutaneous metastatic Crohn disease, deep fungal infection, pemphigus vegetans, Fournier gangrene, neoplastic conditions, erosive LP, trauma, and factitious damage (Badgwell and Rosen, 2006). Treatment includes a combination of local and systemic corticosteroid therapy with or without adjunctive immunosuppressants (i.e., cyclosporine) (Chow and Ho, 1996). Minocycline, sulfasalazine, and thalidomide have been used in combination with corticosteroids in a small number of cases. Genital PG may also be amenable to topical treatment with calcineurin inhibitors (Lally et al, 2005).

Traumatic Causes

Cutaneous lesions of the genitalia, including ulceration, can be caused by local trauma, which should be included in the differential diagnosis. This can be either accidental ("innocent trauma") or self-inflicted ("factitial dermatitis" or "dermatitis artefacta"). Accidental injuries may be a result of trauma during sexual practices (including genital bite wounds), ornamentation (i.e., piercing), or unusual hygiene practices (i.e., cleaning) (Margolis, 2002). Factitial dermatitis is a psychocutaneous disorder in which the individual self-inflicts cutaneous lesions usually for an unconscious motive or because of an underlying mental illness (Fig. 16-20). Factitial lesions are occasionally produced deliberately with the hope of some secondary gain (such as product liability litigation). An association between factitial dermatitis and borderline personality disorder appears to exist (Koblentzer, 2000). Other disorders to be considered include Munchausen syndrome by proxy, body

Figure 16-19. Pyoderma gangrenosum involving the inner thigh of a woman with rheumatoid arthritis (A) and the penis and scrotum (B). (A, From du Vivier A. *Atlas of clinical dermatology*. Figure 16-20. Factitial ulcer of the scrotum caused by repeated picking at the scrotal skin.

dysmorphic disorder, and malingering, if secondary-gain issues exist. Although rare, factitial dermatitis should always be considered in the differential diagnosis of unusual genital lesions, including oddly configured erosions and ulcerations (Verma et al, 2012).

INFECTIONS AND INFESTATIONS

Sexually Transmitted Diseases

STDs with genital cutaneous manifestations include lymphogranuloma venereum, granuloma inguinale, herpes simplex, chancroid, molluscum contagiosum, HPV, and syphilis (Fig. 16-21). These conditions are discussed in detail in Chapter 15.

Balanitis and Balanoposthitis

Balanitis is an inflammatory disorder of the glans penis. When the process involves the preputial skin in uncircumcised men, it is termed balanoposthitis. In children, bacterial infections are the predominant cause. In adult men, the cause may be intertrigo, ICD,

local trauma, or candidal and bacterial infections (Fig. 16-22). Treatment includes removal of irritating agents, improved hygiene, topical antibiotics and antifungals, and occasionally short courses of low-potency topical corticosteroids (Margolis, 2002). When treatment fails, the differential should include neoplastic diseases, Zoon balanitis, psoriasis, and alternative infectious agents such as HPV (Wikstrom et al, 1994). Balanoposthitis tends to occur in patients with phimosis and circumcision may be curative in select recurrent cases. Balanoposthitis may also result from bacterial superinfection in the setting of poor hygiene and neutropenia (Manian and Alford, 1987).

Cellulitis and Erysipelas

Cellulitis is an infection of the deep dermis and subcutaneous tissues most commonly caused by gram-positive organisms (*S. pyogenes* and *S. aureus*) (Lewis, 1998). In immunocompetent individuals, organisms usually gain entry to the site of infection through a break in the skin barrier. In immunocompromised patients, a blood-borne route of infection is more common. Systemic signs of illness include fever, chills, and general malaise. Local signs include erythema (rubor), warmth (calor), pain (dolor), and swelling (tumor) at the site with indistinct borders (Fig. 16-23). Treatment includes systemic antibiotics with activity against *S. pyogenes* and *S. aureus* species. The clinician may be forced to rely on known local antimicrobial sensitivity patterns, because obtaining satisfactory material for culture may be difficult. In cases associated with diabetes, mixed flora may be present and antibiotic coverage should be broadened. Marking the zone of cellulitis at the onset of therapy is an important step to allow progression and resolution of cellulitis to be monitored during therapy.

Erysipelas is a superficial bacterial skin infection limited to the dermis with lymphatic involvement. This disease commonly occurs at the extremes of age and often involves the face. In contrast to the cutaneous lesion of cellulitis, erysipelas generally exhibits a raised and distinct border at the interface with normal skin. The causative organism is usually *S. pyogenes*.

Fournier Gangrene (Necrotizing Fasciitis of the Perineum)

Fournier gangrene (FG) is a potentially life-threatening progressive infection of the perineum and genitalia (Morpurgo and Galandiuk, 2002). In the genital region, most cases of FG are caused by mixed

Figure 16-21. Genital lesions associated with sexually transmitted diseases. A, Herpes simplex virus. B, Molluscum contagiosum. C, Syphilitic chancre. D, Granuloma inguinale. E, Chancroid. F, Lymphogranuloma venereum. G, Condyloma accuminata. (From Callen JP, Greer DE, Hood AF, et al. *Color atlas of dermatology*. Philadelphia: Saunders; 1993.)

bacterial flora, which include gram-positive, gram-negative, and anaerobic bacteria. *Escherichia coli*, *Bacteroides* spp., *S. pyogenes*, and *S. aureus* are common etiologic pathogens. Risk factors for developing FG include underlying alcoholism, diabetes, cancer and malnutrition, advanced age, recent urogenital or colorectal instrumentation or trauma, and preexisting peripheral vascular disease. However, group A streptococcal necrotizing fasciitis can occur in healthy immunocompetent individuals.

The hallmark of FG is a rapid progression from the signs and symptoms of cellulitis (erythema, swelling, and pain) to blister formation, to clinically visible ischemia, and ultimately to foul-smelling necrotic lesions (Fig. 16-24). Infection may spread along fascial planes and hence the exterior skin findings may represent only a small proportion of the underlying infected and necrotic tissue. The diagnosis of FG is a surgical emergency, as progression from genitalia to perineum to abdominal wall may occur

Figure 16-22. Candidal balanoposthitis. (From Korting GW. *Practical dermatology of the genital region*. Philadelphia: Saunders; 1981. p. 159.)

Figure 16-23. Penoscrotal cellulitis. (From Korting GW. *Practical dermatology of the genital region*. Philadelphia: Saunders; 1981. p. 37.)

extremely rapidly (often within hours). Spread of tissue infection is accompanied by an ever-increasing risk of bacterial septicemia, usually the eventual cause of death. The exclusion of FG therefore should be a priority during every consultation for soft tissue infection of the genitalia. Pain out of proportion to

Figure 16-24. Fournier gangrene of the scrotum. A, Surface appearance of scrotum and perineum showing area of frank necrosis. B, Extent of soft tissue debridement required to achieve margins of viable tissue. Note that the testes within their tunica vaginalis compartment are spared.

the visible extent of infection should raise suspicion for FG. The skin may also exhibit a grayish cast or fetid odor uncharacteristic of uncomplicated genital cellulitis. Imaging of the genitalia with plain radiographs, computed tomography, and/or bedside ultrasonography (Amendola et al, 1994; Avery and Scheinfeld, 2013) may demonstrate gas bubbles within the tissue, although the delay associated with imaging should not postpone surgical intervention in obvious cases.

Treatment involves a combination of broad-spectrum antibiotics and extensive surgical debridement to margins of healthy bleeding tissue. These patients will often require a second-look operation after 24 to 48 hours to exclude further disease progression (Gurdal et al, 2003). During surgical debridement for scrotal FG, the testicles and other structures within the tunica vaginalis can almost always be spared, although loss of tissue in the abdominal wall may be extensive because of bacterial spread along fascial planes. The indications for adjunctive hyperbaric oxygen therapy in FG remain controversial, although several groups have reported favorable results (Dahm et al, 2000; Eke, 2000; Jallali et al, 2005). There may also be potential benefit to the use of vacuum-assisted closure devices in FG (Czymek et al, 2009). However, despite aggressive modern management, the mortality of FG may be as high as 16% to 40% (Dahm et al, 2000; Eke, 2000; Blume et al, 2003; Yenyol et al, 2004; Sorensen et al, 2009). A number of different numeric scoring scales have been applied to FG in an attempt to predict proactively the patients who are at the highest risk for mortality and who should receive the most aggressive intervention. These include the FG Severity Index and the Uludag FG Severity Index, as well as the more general Age-Adjusted Charlson Comorbidity Index (ACCI) and the recently introduced surgical Apgar Score (sAPGAR). A study verified that *all* of these scoring systems are valid methods for assessing patients in the setting of FG, and adoption of one may assist the clinician in making therapeutic decisions (Vyas et al, 2013).

Among patients who survive an episode of FG, there most likely will be ongoing disability and reduced functionality for months to years. Sexual dysfunction is quite common (~65%) (Czymek et al, 2013). Therefore FG survivors should expect to receive long-term care from a variety of specialists.

Folliculitis

Folliculitis is a common disorder characterized by perifollicular pustules on an erythematous base (Kelly, 2003). It occurs most

Figure 16-25. Pseudomonal folliculitis caused by the use of a hot tub. (From Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003. p. 554.)

frequently in heavily hair-bearing areas such as the scalp, beard, axilla, groin, and buttocks and can be exacerbated by local trauma from prolonged occlusion (e.g., truck drivers), shaving, rubbing, or clothing irritation (Margolis, 2002). Patients may complain of pruritus or pain over the area; conversely, symptoms may be entirely absent. Cultures are generally negative, although a variety of infectious organisms have been associated with folliculitis including *S. aureus*, *Pseudomonas* spp., fungi, and herpes simplex virus. Folliculitis has also been associated with the use of contaminated hot tubs and swimming pools, with the offending organism usually *Pseudomonas aeruginosa* (Fig. 16-25) (Gregory and Schaffner, 1987; Rolston and Bodey, 1992). Treatment for folliculitis includes good hygiene, removal of offending irritants, and appropriate topical or systemic antiviral, antibiotic, or antifungal agents. The results of a

surveillance study indicate that 96% of *P. aeruginosa* isolates tested from swimming pools and hot tubs were multidrug resistant (Lutz and Lee, 2011). These results may have important implications for immune-suppressed individuals, where infection with multidrug-resistant *P. aeruginosa* has a greater potential impact. Failure to respond to conservative measures should lead to lesion culture with concomitant antimicrobial susceptibility testing.

Furunculosis

Both furuncles and abscesses are walled-off collections of pus. Although abscesses can occur anywhere on the body, a furuncle is by definition associated with a hair follicle. Furuncles tend to occur in areas prone to minor trauma including the groin and buttocks (Fig. 16-26). *S. aureus* is the most common causative organism although anaerobes may be present. Risk factors include diabetes mellitus, obesity, poor hygiene, and immunosuppression (Brook and Finegold, 1981). Warm compresses may be beneficial, and larger lesions may require incision and drainage, as for any abscess. When there is associated cellulitis, a systemic antibiotic with activity against staphylococci should be administered. In today's environment of methicillin-resistant staphylococci, coverage for such organisms is advisable if they are prevalent within the clinician's community.

Hidradenitis Suppurativa (Acne Inversa)

Hidradenitis suppurativa (HS) is a chronic disease of apocrine gland-bearing skin with a predilection for the axillae and anogenital regions (Kelly, 2003; Alikhan et al, 2009). The condition generally begins after puberty and a familial form with an autosomal dominant pattern of inheritance has been described (Von Der Werth et al, 2000). Originally believed to be a disease of apocrine glands, HS is now thought to be an epithelial disorder of hair follicles (Jansen et al, 2001). Although superinfection of HS lesions may occur, bacterial infection does not appear to be the primary initiator. During the pathogenesis of HS, hair follicles become plugged and swollen. Rupture of follicular contents (including bacteria and keratin) into the surrounding dermis initiates a marked inflammatory response with the formation of abscesses and sinus tracts (Slade et al, 2003).

Figure 16-26. A large furuncle located on the buttocks. (From Habib TP. Clinical dermatology: Edinburgh: Mosby; 2004. p. 284.)

The clinical features of HS include painful inflammatory nodules and sterile abscesses developing in the axillae, groin, perianal, and inframammary areas (Fig. 16-27) (Kelly, 2003). With time, draining sinus tracts and hypertrophic scars develop. Serious complications of HS can occur, including hypoproteinemia, secondary amyloidosis, the development of fistulae to the urethra (Gronau and Pannek, 2002), bladder, peritoneum and rectum (Nadgir et al, 2001), and SCC in areas of heavy scarring (Altunay et al, 2002; Rosenzweig et al, 2005).

Treatment of HS includes improvement in hygiene, weight reduction, and efforts to minimize friction and moisture in affected areas (i.e., loose undergarments, absorbent powder) (Kelly, 2003). No single therapeutic intervention is universally effective. Topical clindamycin or the combination of oral clindamycin or minocycline with oral rifampicin may be beneficial for some patients (Gener et al, 2009). In a double-blind randomized trial, systemic therapy with tetracycline was no more effective than topical clindamycin in HS (Jemec and Wendelboe, 1998). Other oral agents that sometimes prove beneficial include dapsone (50 to 200 mg/day), zinc (40 to 80 mg/day elemental zinc), retinoids (acitretin 25 to 50 mg/day or isotretinoin 1 mg/kg/day), cyclosporine (4 mg/kg/day), and hormone blockers (spironolactone and oral contraceptives in women and finasteride and dutasteride in men) (Scheinfeld, 2013a). Systemic corticosteroids may improve HS, but relapse is the rule after cessation of therapy (Slade et al, 2003). Lithium may exacerbate HS or limit its response to conventional medical therapy (Gupta et al, 1995). Although recurrent incision and drainage of HS lesions are discouraged, wide and deep excision with skin grafting has been effective (Rompel and Petres, 2000; Bocchini et al, 2003). A variety of new approaches, including the use of the CO₂ and Nd:YAG lasers to treat HS, are under investigation (Lapins et al, 1994; Madan et al, 2008; Tierney et al, 2009). Off-label administration of TNF- α blockers (particularly subcutaneous adalimumab: 40 mg/wk) has proven variably effective in the management of HS in select patients when surgery is simply not feasible (Shuja et al, 2010).

Corynebacterial Infection (Trichomycosis Axillaris and Erythrasma)

Trichomycosis axillaris is a superficial bacterial infection of axillary and pubic hair caused by corynebacteria. Yellow, red, or black nodules are visible on the hair shafts (Fig. 16-28) and there is frequently a characteristic odor (Blume et al, 2003). There is an association with hyperhidrosis (Margolis, 2002). The differential diagnosis includes infestation with pediculosis pubis or fungal infection (piedra) (Avram et al, 1987), although examination with magnification can generally distinguish trichomycosis axillaris from these conditions. Shaving can provide immediate improvement, and antibacterial soaps may prevent further infection (Blume et al, 2003). For pubic trichomycosis axillaris, clindamycin gel, bacitracin, and oral erythromycin have also proven effective (Bargman, 1984; Blume et al, 2003).

Erythrasma is a *Corynebacterium minutissimum* infection of the skin that results in sharply bordered, light red to dark brown, scaling patches in moist areas, particularly the groin and axilla. These lesions may be pruritic or asymptomatic and may be confused with dermatophyte infection (tinea cruris) (Sindhuphak et al, 1985). Under a Wood light, the lesions show a characteristic bright coral-red fluorescence (see Fig. 16-28) (Halprin, 1967). Effective treatments include antibacterial soaps, topical aluminum chloride, topical clindamycin 1% solution or gel, miconazole 1% cream, and oral erythromycin (500 to 1000 mg/day) (Cochran et al, 1981; Holdiness, 2002).

Ecthyma Gangrenosum

Ecthyma gangrenosum is a rare cutaneous manifestation of pseudomonal septicemia that presents most commonly on the

Figure 16-27. Hidradenitis suppurativa. A, Characteristic painful papules and draining sinus tracts. B, Histology shows follicular plugging and connection to a dilated apocrine duct. C and D, Examples of severe genital involvement of hidradenitis, which would make surgical management difficult. (A, From du Vivier A. *Atlas of clinical dermatology*. London: Churchill Livingstone; 2002. p. 712; B, from Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Saunders; 2008. Fig. 39.13.)

anogenital area in debilitated, immunosuppressed, or neutropenic patients. The lesions of ecthyma gangrenosum are tender grouped erythematous macules that may progress to form bullae or rupture to produce a gangrenous ulcer covered by a thick, black eschar (Fig. 16-29) (Blume et al, 2003). On histologic examination, necrotizing vasculitis and gram-negative organisms are present. The differential diagnosis includes PG, necrotizing vasculitis, cryoglobulinemia, and septic emboli containing other organisms including *Candida*, *Aspergillus*, *Citrobacter*, *E. coli*, *Aeromonas hydrophila*, and *Fusarium* (Altwegg and Geiss, 1989; Martino et al, 1994; Gucluer et al, 1999; Reich et al, 2004). Consistent with the underlying sepsis, ecthyma gangrenosum carries a poor prognosis and immediate treatment with intravenous antipseudomonal antibiotics is

indicated. Wound debridement may also be necessary (Collini et al, 1986).

Genital Bite Wounds

Following deliberate or accidental bite wounds to the genitalia, a normal component of the human oral flora, *Eikenella corrodens*, may be implanted into genital skin. This results in the rapid development of extremely painful, necrotic ulcerations at the bite site(s) (Fig. 16-30) (Rosen and Conrad, 1999; Rosen, 2005). The rapidity of ulceration, extraordinary degree of discomfort, and a history of traumatic orogenital contact help distinguish this type of infection from the more common STDs and other genital ulcers. The

Figure 16-28. Corynebacterial infections of the skin. A, Trichomycosis axillaris. B and C, Erythrasma under white light (B) and Wood lamp (C) showing coral-red fluorescence. (From Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003.)

treatment is high-dose oral amoxicillin-clavulanate (1500 mg/day) until healing occurs.

Candidal Intertrigo

Fungal infection of macerated skin folds can occur with candidal species and involve the finger webs and intertriginous areas. Affected pruritic skin is reddened and characteristic satellite lesions may be present (Fig. 16-31). The differential diagnosis includes dermatophyte infection (tinea cruris), pemphigoid, psoriasis, SD, and contact dermatitis (Margolis, 2002). Fungal forms (round yeast cells as well as elongate pseudohyphae) can be seen in scraped skin preparations after treatment with KOH, and culture is usually unnecessary. Daily topical treatment with any imidazole antifungal agent for at least 2 weeks is usually necessary for intertrigo, and oral antifungals (such as fluconazole 150 mg/day) are occasionally required (Cullin, 1977). Maneuvers to decrease moisture and skin maceration, such as the use of drying powders and loose clothing, may also help prevent relapse. Candida intertrigo may be a presenting sign of diabetes, and appropriate laboratory testing should be performed to rule this out as a predisposing condition.

Dermatophyte Infection

Dermatophytes are fungi of three genera (*Trichophyton*, *Microsporum*, *Epidermophyton*) that have the propensity to invade and grow within keratinized tissues such as the skin, hair, and nails. These fungi produce keratinases, which break down keratin and facilitate invasion (Viani et al, 2001). In addition, mannans in the cell wall of some dermatophytes produce immunoinhibitory effects (Dahl, 1994).

Tinea cruris is the term applied to dermatophyte infection of the groin and genital area and is commonly known as “jock itch.” More common in males than females, this condition is favored by hot, humid environments and concomitant dermatophyte infection of the feet (*tinea pedis*). Obesity may also be a significant risk factor (Scheinfeld, 2004). The inner thighs and inguinal region are the most commonly affected areas and the scrotum and penis are usually spared in men. However, isolated penile dermatophytosis has been well described (Pielop and Rosen, 2001). Conversely, significant scrotal involvement should raise suspicion for cutaneous candidiasis as an alternative diagnosis (Sobera and Elewski, 2003). Characteristic lesions in tinea cruris are sharply demarcated with a raised erythematous border

Figure 16-29. Ecthyma gangrenosum. A, Involvement on the chest wall. Note the necrotic center and erythematous border around the lesion. B, Histologically, necrotic vessels surrounded by a “blue haze” of organisms characterize ecthyma gangrenosum. (A, From Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003. p. 1132; B, from Elston DM, Ferringer T. *Dermatopathology*. Edinburgh: Saunders; 2009. p. 263.)

Figure 16-31. Candidal intertrigo with erythema, areas of tissue maceration, and satellite lesions. (From Callen JP, Greer DE, Hood AF, et al. *Color atlas of dermatology*. Philadelphia: Saunders; 1993. p. 318.)

(Fig. 16-32) and they may be intensely pruritic. A variety of disorders can mimic dermatophytes infection including SD, psoriasis, contact dermatitis and erythrasma. The diagnosis of fungal infection can be confirmed with skin scrapings and a KOH preparation. Culture is rarely required, as organisms are easily visualized microscopically.

Good hygienic practices can be beneficial in preventing recurrent disease, including wearing loose clothing, cleaning of contaminated garments, weight reduction, and the use of topical powders to keep the intertriginous areas dry (Sobera and Elewski, 2003). Topical antifungal preparations are the primary agents for treatment, with the powdered forms having the added benefit of drying moist areas. Care should be taken to treat only active disease and not the postinflammatory hyperpigmentation that can occur with recurrent chronic dermatophyte infection (Margolis, 2002). Systemic antifungals are rarely necessary to treat groin infection with dermatophytes. However, should this prove necessary, the current drug of choice is terbinafine in a dose of 250 mg/day for 1 week (Farag et al, 1994).

Infestation

Pediculosis pubis and scabies (*Sarcoptes scabiei*) are the most common infestations involving the genital region.

Infestation with the crab louse (*Phthirus pubis*) causes pediculosis pubis, a pruritic disorder of the genitalia, which may coexist with other STDs (Opaneye et al, 1993; Varela et al, 2003). In one study of adolescent males, patients with pediculosis pubis showed a risk of concomitant gonorrhea or chlamydial infection more than twofold higher than normal controls (Pierzchalski et al, 2002). Louse infestation is not limited to the genitals and may involve other hair-bearing areas such as the eyelashes, beard, and axillae (Meinking, 1999). The diagnosis is confirmed by

Figure 16-32. Dermato­phyte infection. A, *Tinea cruris* showing areas of postinflammatory hyperpigmentation and active infection at the border of the lesions. B, Histologically, fungal hyphae are localized within a compact stratum corneum layer. C, Potassium hydroxide preparation from a scraping showing fungal forms. (A, From Callen JP, Greer DE, Hood AF, et al. Color atlas of dermatology. Philadelphia: Saunders; 1993. p. 318; B and C, from Elston DM, Ferringer T. Dermatopathology. Edinburgh: Saunders; 2009. p. 275.)

Figure 16-33. Pediculosis pubis. Several crab lice are visible. (From du Vivier A. Atlas of clinical dermatology. London: Churchill Livingstone; 2002. p. 338.)

identification of crab lice attached to hairs (Fig. 16-33), often with associated perifollicular erythema. Transmission of pediculosis pubis is usually through sexual contact, although contaminated clothing, bedding, and towels have also been implicated in some cases (Meinking, 1999). The standard treatment is the application of 5% permethrin cream overnight to all affected hair-bearing areas with a repeat application 1 week later (Meinking et al, 2003). Note that the second application of permethrin is important, as the rate of treatment success with

a single application may be as low as 57% (Kalter et al, 1987). For rare cases refractory to topical therapy or those involving the eyelashes (*tinea palpebrarum*), the addition of oral ivermectin may be curative (Burkhart and Burkhart, 2000). Interestingly, because of the adoption of the widespread removal of pubic hair among young adults of both genders ("Brazilian waxing"), the incidence of pubic louse infestation in industrialized countries has fallen dramatically in recent years.

Another important infestation involving the genitalia is scabies, caused by the female itch mite *Sarcoptes scabiei*. Scabies is a world-wide problem and factors such as overcrowding, delayed treatment of primary cases, and poor public awareness encourage spread (Meinking et al, 2003). Transmission is common between close contacts and family members (Burkhart et al, 2000). The number of mites living on an immunocompetent host is usually small (<100) (Arlan et al, 1988), although far greater numbers may be recovered in cases of immunosuppression (so-called crusted or Norwegian scabies). The incubation period before symptoms develop after infestation can vary from days to months in duration, but is most typically about 6 weeks.

Severe pruritus is the hallmark of scabies, often accentuated at night or after bathing (Meinking et al, 2003). In both genders, the genital areas are commonly affected. Small erythematous and pruritic papules are present, and excoriations with secondary bacterial infection may occur (Fig. 16-34). Thin, gray or white burrows may be visible and are pathognomonic for scabies infestation. Crusted scabies affecting genital skin presents as it does in other anatomic sites: with thickly crusted plaque(s) (Perna et al, 2004). In the absence of visible burrows, a broad differential must be considered including AD, pyoderma, psoriasis, and other insect bites. As in the case of pediculosis pubis, the

Figure 16-34. Scabies. A, A papular eruption with visible characteristic burrows (arrow). B and C, Classic established genital scabies with eroded papules on the glans penis and scrotum. (A, From du Vivier A. *Atlas of clinical dermatology*. London: Churchill Livingstone; 2002. p. 332; B and C, from Habif TP. *Clinical dermatology*. Edinburgh: Mosby; 2004. p. 501.)

treatment of choice for scabies is 5% permethrin cream applied to the entire body overnight with a second application 1 week later. An alternative topical scabicide, lindane, is not favored because of both central nervous system toxicity in children and a rising rate of resistance among mites (Purvis and Tyring, 1991; Elgart, 1996; Boix et al, 1997). Oral ivermectin (200 µg/kg/dose, 2 doses administered 2 weeks apart) is an alternate regimen that has been successfully used to treat scabies (Chouela et al, 2002; Heukelbach et al, 2004; Karthikeyan, 2005). A randomized comparative trial showed that permethrin was slightly more effective than ivermectin when the latter is only provided as a single dose (Goldust et al, 2012). Note that pruritus may persist for several weeks despite successful treatment and that all intimate contacts should also be treated to prevent reinfection. Even with effective treatment, itchy nodules may remain on the glans penis; intralesional injections of minute amounts of dilute triamcinolone acetonide (2 to 3 mg/mL) may facilitate resolution of these post-scabies nodules.

NEOPLASTIC CONDITIONS

Squamous Cell Carcinoma in Situ

Squamous cell carcinoma in situ (SCCis) is a full thickness intraepithelial carcinoma (Miller and Moresi, 2003). Bowen originally described this condition in 1912, hence the term “Bowen disease” (Bowen, 1912). On extragenital sites, there is a strong association between SCCis and ultraviolet light exposure (Reizner et al, 1994). Commonly presenting in the seventh decade of life with a slight female predominance (Hemminki and Dong, 2000; Arlette, 2003), SCCis usually has an indolent clinical course and rarely progresses to invasive disease. When it occurs on mucosal surfaces of the male genitalia, most notably the glans penis of uncircumcised men, this entity is referred to as erythroplasia of Queyrat (Fig. 16-35). Yet another name for this entity is penile intraepithelial neoplasia. In the female, the comparable SCCis on the vulva would be called vulvar intraepithelial neoplasia. In these locations,

coinfection with HPV types 8, 16 (70%), and other serotypes (30%) has been identified (Wieland et al, 2000). Other risk factors for SCCis include ionizing radiation, immunosuppression, thermal injury, arsenic exposure, chronic dermatoses (such as long-standing LP), and LS of the glans penis (Euvrard et al, 1995; Nasca et al, 1999; Powell et al, 2001; Centeno et al, 2002; Arlette, 2003).

SCCis lesions are sharply demarcated, solitary, pink to red scaly plaques, which may be confused with basal cell carcinoma, eczema, seborrhea, or psoriasis. SCCis on or near the vulva may be heavily pigmented and resemble both melanoma and external genital warts. When localized to the penile shaft, SCCis may have a more thickened, verrucoid appearance. Although usually asymptomatic, these lesions may also be pruritic or painful. The diagnosis is confirmed by histologic evaluation and several areas should be sampled to exclude the presence of dermal invasion (Margolis, 2002).

Figure 16-35. Erythroplasia of Queyrat. Squamous cell carcinoma involving the glans penis. (From Callen JP, Greer DE, Hood AF, et al. Color atlas of dermatology. Philadelphia: Saunders; 1993. p. 330.)

Primary treatment of SCCis involves either surgical excision or tissue ablation. For accessible areas, such as the scrotum, simple excision with a 5-mm margin is favored (Bissada, 1992; Margolis, 2002). For areas where tissue preservation is more critical, Mohs microsurgery, laser therapy, and cryoablation may play a role (Sonnex et al, 1982b; van Bezooijen et al, 2001; Leibovitch et al, 2005). Topical treatment with either 5-fluorouracil or imiquimod 5% has also proven effective for management of selected cases of SCCis involving the genitalia (Gerber, 1994; Orenge et al, 2002; Arlette, 2003; Micali et al, 2003).

Bowenoid Papulosis

Bowenoid papulosis is an uncommon condition found on the penis and vulva of sexually active adults, with a peak incidence in the third decade of life (Schwartz and Janniger, 1991). It histologically resembles Bowen disease except that the abnormal keratinocytes are spread discontinuously throughout the epidermis (Margolis, 2002). Typical lesions are multiple small erythematous papules that may coalesce to form plaques with a verrucous surface similar to a genital wart (Fig. 16-36). There is a clear association with HPV type 16. Female partners of men with bowenoid papulosis have an increased risk of cervical neoplasia and should receive close cervical follow-up (Rosemberg et al, 1991). In men, however, bowenoid papulosis generally has a benign course and spontaneous regression may occur (Eisen et al, 1983; Giam and Ong, 1986; Feng et al, 2013). Therefore, in a young and reliable patient, observation alone may be justified. If treatment is desired, conservative local therapy with topical agents (0.5% 5-fluorouracil, 0.5% tazarotene cream, or imiquimod 5%) or ablative measures (electrodessication, liquid nitrogen cryotherapy, laser ablation) is usually appropriate (Margolis, 2002).

Squamous Cell Carcinoma

Invasive SCC involving the genitalia (Fig. 16-37) is covered in detail in Chapter 37.

Figure 16-36. Bowenoid papulosis. A, Involvement of the penile shaft. Note multiple brown verrucous papules on the penile shaft. Edinburgh: Saunders; 2009. p. 57.)

Figure 16-38. Verrucous carcinoma of the penis (Buschke-Lowenstein tumor). A, Note the exophytic and wartlike appearance. B, Histologic features of verrucous carcinoma. (A, From Callen JP, Greer DE, Hood AF, et al. *Color atlas of dermatology*. Philadelphia: Saunders; 1993. p. 330; B, from Elston DM, Ferringer T. *Dermatopathology*. Edinburgh: Saunders; 2009. p. 58.)

Verrucous Carcinoma (Buschke-Lowenstein Tumor)

Verrucous carcinoma is a locally aggressive, exophytic, low-grade variant of SCC that has little metastatic potential (Habif, 2004). The Buschke-Lowenstein tumor is a verrucous carcinoma of the anogenital mucosal surface and may represent up to 24% of all penile tumors (Schwartz, 1995). It most commonly occurs in uncircumcised men on the glans or prepuce, although similar lesions can be found on the vulva, vagina cervix, or anus. Verrucous carcinoma has been associated with HPV type 6 and 11 infection but not with the more classically oncogenic types 16 and 18 (Yasunaga et al, 1993; Chan et al, 1994; Margolis, 2002; Ahmed et al, 2006).

Verrucous carcinoma lesions have a warty appearance and are often large and fungating when presenting on the genitalia (Fig. 16-38). Aside from genital sites, these lesions can also present within the oral and nasal cavities and plantar surfaces of the feet. They are slow growing and locally destructive, often extending deeply into underlying tissue. Preferred treatment is by local excision. Mohs micrographic surgery may be helpful in tracing out the tumor and minimizing tissue loss. Primary radiotherapy is relatively contraindicated because of the potential for anaplastic transformation with a subsequent increase in metastatic potential (Stehman et al, 1980; Andersen and Sorensen, 1988; Fukunaga et al, 1994; Vandeweyer et al, 2001).

Basal Cell Carcinoma

Basal cell carcinoma (BCC) is the most common cutaneous neoplasm overall, arising most often on areas of chronically sun-exposed skin such as the head and neck. Genital BCC has also been described as a very rare entity, most commonly involving the scrotal skin in the male and the vulva in the female (Nahass et al, 1992; Benedet et al, 1997; Esquivias Gomez et al, 1999; Kinoshita et al, 2005). In the world medical literature, to date fewer than 100 total cases of BCC have been described involving all the potential genital sites (penis, scrotum, vulva). Several subtypes of BCC have been defined including nodular, superficial, micronodular morpheaform, and infiltrating. The nodular variant accounts for 60% of extragenital BCCs and virtually all genital BCCs, and this variant presents as a pearly, skin-toned papule or plaque often with telangiectasias overlying the tumor (Fig. 16-39) (Miller and Moresi,

Figure 16-39. Basal cell carcinoma involving the vulva. (From du Vivier A. *Atlas of clinical dermatology*. London: Churchill Livingstone; 2002. p. 688.)

2003). These lesions may ulcerate centrally and manifest a very low metastatic potential. Treatment is by local excision. Because preservation of genital skin is important, both for form and function, the use of Mohs micrographic surgery may be advisable for the rare genital BCC.

Kaposi Sarcoma

Kaposi sarcoma (KS) is a disease of endothelial cell origin. Whether KS is a neoplastic or hyperplastic process remains controversial, and evidence exists both for and against clonal expansion (Rabkin et al, 1997; Gill et al, 1998). Before the onset of the AIDS epidemic, KS was considered a chronic disease afflicting elderly men of Jewish, Mediterranean, or Eastern European descent ("classic KS") (Safai, 1987). However, infection with HIV-1 has increased the incidence of KS by more than 7000-fold (Miles, 1994; Margolis, 2002). KS generally affects HIV-infected patients with advanced immune impairment (CD4+ T-cell counts of <500 cells/mm) (Tappero et al, 1993). Approximately 40% of homosexual men with AIDS have developed KS as compared to less than 5% in other risk groups (Rogers et al, 1987; North et al, 2003). There is also a clear association between infection with human herpesvirus 8 and the development of KS (Boshoff and Weiss, 1997; Weiss et al, 1998). In this regard, the other group at risk for development of KS associated with human herpesvirus 8 infection includes recipients of solid organ transplants (Riva et al, 2012).

Classic KS in immunocompetent individuals presents as slowly growing, blue-red to overtly violaceous pigmented macules on the lower extremities. Although oral and gastrointestinal lesions may occur, the genitalia are seldom involved. This is in contrast to the case with AIDS ("epidemic KS") in which a solitary genital lesion may be the first manifestation of KS (Lowe et al, 1989). The clinical features of KS in both AIDS patients and solid organ transplant recipients are diverse, ranging from a single lesion to disseminated cutaneous and visceral disease (Fig. 16-40). Lesions may coalesce to cover large areas of skin and may result in lymphatic or venous blockage leading to local edema (Margolis, 2002). When these lesions involve the glans penis, they can cause obstruction at the urethral meatus or fossa navicularis (Swierzewski et al, 1993). It should be noted, however, that penile KS is still rare, even among those infected with HIV-1; only about 3% of AIDS patients will ever develop KS of the genitalia (Rosen et al, 1999).

Treatment must be tailored to the individual clinical case and complete cure may be an unrealistic goal. For solitary lesions, local

Figure 16-40. Kaposi sarcoma. Classic macular lesions seen on the back (A) and glans penis (B). (A, From Callen JP, Greer DE, Hood AF, et al. *Color atlas of dermatology*. Philadelphia: Saunders; 1993. p. 220; B, from du Vivier A. *Atlas of clinical dermatology*. London: Churchill Livingstone; 2002. p. 716.)

therapy such as surgical excision, laser ablation, cryotherapy, topical imiquimod 5%, or intralesional injection of chemotherapeutic agents (i.e., vinblastine) may be beneficial (Chun et al, 1999; Schwartz, 2004; Heyns and Fisher, 2005; Rosen, 2006). For extensive locoregional disease, radiotherapy (15 to 30 Gy) has an objective response rate of greater than 90% (Kirova et al, 1998; Cattelan et al, 2002). For widely disseminated KS, systemic chemotherapy with vincristine, doxorubicin, and bleomycin is the treatment of choice (Aversa et al, 1999). For KS associated with organ transplantation, reduction in the degree of postoperative immunosuppression or switching from a calcineurin inhibitor to an mTOR inhibitor may lead to KS resolution without any additional intervention (Riva et al, 2012).

Pseudoepitheliomatous, Keratotic, and Micaceous Balanitis

Pseudoepitheliomatous, keratotic, and micaceous balanitis (PEKMB) is a rare entity characterized by the development of a thick, hyperkeratotic plaque on the glans penis of older men (Fig. 16-41). The term *micaceous* refers to the white, scaly appearance of the lesions (Child et al, 2000). PEKMB was originally thought to be a purely benign process, although several case reports have documented the presence of concurrent verrucous carcinomas associated with this lesion (Child et al, 2000). Controversy remains as to whether PEKMB is a premalignant condition (Read and Abell, 1981; Beljaards et al, 1987; Jenkins and Jakubovic, 1988). Histologic examination is essential to exclude the presence of SCC and verrucous carcinoma (Margolis, 2002). PEKMB is characterized on histology by a hyperplastic epidermis with ridges extending deeply into the dermis (Jenkins and Jakubovic, 1988). These lesions should be treated locally either by surgical excision or ablative techniques, and close follow-up is essential (Read and Abell, 1981; Bargman, 1985). There are also anecdotal reports of successful treatment using topical 5-fluorouracil cream (Bargman, 1985; Kronic et al, 1996).

Melanoma

Malignant melanoma is a neoplasm arising from melanocytes. The incidence of melanoma has risen 3% to 7% during the past several decades (Nestle and Kerl, 2003). Risk factors for development of the disease include family history, certain genetic markers, fair skin, light eye color, and a history of excessive ultraviolet radiation exposure (especially multiple blistering sunburns as a child or adolescent). Primary melanoma of the male genitalia is an uncommon entity with only approximately 100 cases reported in the literature (Sanchez-Ortiz et al, 2005) and melanoma of the male urethra is even more rare (Oliva et al, 2000). The same cannot be said for

Figure 16-41. Pseudoepitheliomatous, keratotic, and micaceous balanitis. The glans becomes covered with mica (asbestos-like) scales and horny crusts. (From du Vivier A. Atlas of clinical dermatology. London: Churchill Livingstone; 2002. p. 717.)

females, as melanoma comprises about 7% to 10% of all vulvar malignancies and remains the second most common such lesion after SCC (Suwandinata et al, 2007). Although vulvar melanoma is more common among Caucasian women, the prognosis is worse among African-American women (Mert et al, 2013).

Genital melanoma usually presents as a pigmented macule or papule with an irregular border, although unpigmented lesions and ulceration may also be present (Margolis, 2002). Early diagnosis is critical because local treatment of superficial lesions with wide local excision or partial penectomy can provide excellent disease control (Stillwell et al, 1988; Sanchez-Ortiz et al, 2005). The same caveats are true in female patients. In contrast, patients with biopsy-proven metastatic disease have traditionally had a universally poor prognosis despite aggressive surgical management and multiagent cytotoxic chemotherapy. In the last several years, however, several drugs have gained regulatory approval for the treatment of metastatic and unresectable melanoma as a result of an increase of knowledge in melanoma-specific molecular biology and immunology. The efficacy of small-molecule BRAF (e.g., vemurafenib, dabrafenib, trametinib) and MAP-ERK kinase (MEK) inhibitors, as well as the immune checkpoint inhibitors (e.g., ipilimumab and the anti-PD1/PDL1 antibodies lambrolizumab and nivolumab), have transformed the treatment of advanced melanoma.

Extramammary Paget Disease

Extramammary Paget disease (EPD) is an uncommon intraepithelial adenocarcinoma of sites bearing apocrine glands (Zollo and Zeitouni, 2000). The majority of patients with EPD are elderly Caucasian females, and involvement of the male penis and scrotum is exceedingly rare (Park et al, 2001; van Randenborgh et al, 2002; Yang et al, 2005). The vulva is the most commonly involved genital site in women followed by the perianal region in men (Wojnarowska and Cooper, 2003). There is an important association between EPD and another underlying malignancy in at least 10% to 30% of cases (Payne and Wells, 1994; Ng et al, 2001; Margolis, 2002). An investigation in a cancer specialty hospital suggested that this association might be even stronger in men than previously appreciated (Hegarty et al, 2011). In the male, associations between urethral, prostate, bladder, rectal, and apocrine malignancies with EPD have been described (Hayes et al, 1997; Salamanca et al, 2004; Hegarty et al, 2011). It is critical therefore to perform a systematic evaluation for underlying carcinoma in all cases of EPD.

The lesion in EPD is usually an erythematous plaque with a sharp border between normal and involved skin (Fig. 16-42). It may be asymptomatic, pruritic, or associated with burning pain. The diagnosis is confirmed histologically by the presence of vacuolated Paget cells in the epidermis that stain for glandular cytokeratins, epithelial membrane antigen, and carcinoembryonic antigen (Wojnarowska and Cooper, 2003). Treatment generally involves surgical excision or Mohs micrographic surgery, although radiotherapy, photodynamic therapy, and topical imiquimod 5% or 5-fluorouracil have also been used successfully (Sillman et al, 1985; Bewley et al, 1994; Brown et al, 2000; Brown et al, 2002; Guerrieri and Back, 2002; Moreno-Arias et al, 2003; Qian et al, 2003; Lee et al, 2009).

Cutaneous T-Cell Lymphoma

Cutaneous T-cell lymphoma (CTCL) represents a group of related neoplasms derived from T cells that home to the skin. CTCL includes a variety of conditions including mycosis fungoides, Sézary syndrome, lymphoid papulosis, and pagetoid reticulosis (Willemze, 2003). There is an increased risk of CTCL associated with HIV infection (Biggar et al, 2001). Although these disorders may involve the genitalia of both genders, extragenital disease is usually also present. CTCL accounts for the majority of primary cutaneous lymphomas with B-cell-derived lymphomas accounting for only 20% to 25% (Willemze et al, 1997, 2005). Definitive diagnosis depends on biopsy histopathology.

Figure 16-42. Extramammary Paget disease involving the vulva (A) and base of scrotum (B). Note the well-demarcated border between the lesion and normal adjacent skin. C, Tumor cells distributed throughout the epidermis (“buckshot scatter”). (A, From Habif TP. *Clinical dermatology*. Edinburgh: Mosby; 2004. p. 764; B, from Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003. p. 1108; C, from Elston DM, Ferringer T. *Dermatopathology*. Edinburgh: Saunders; 2009. p. 66.)

CTCL generally presents initially as pruritic patches that must be differentiated from a variety of benign dermatoses including psoriasis, eczema, superficial fungal infections, and drug reactions. The initial lesions of CTCL have a strong predilection in both sexes to occur on suprapubic and/or buttock skin. Patients may subsequently develop hematologic involvement (Sézary syndrome) and cutaneous plaques, erosions, ulcers, or frank skin tumors (Fig. 16-43) (Margolis, 2002). CTCL is a chronic condition that may progress throughout many years. Topical treatments include application of ultrapotent corticosteroids, nitrogen mustard, and carmustine with complete remission rates of approximately 60% (Vonderheid et al, 1989; Zackheim et al, 1998). Other treatments include radiotherapy (including total body electron beam treatment), phototherapy (PUVA), and systemic treatment with chemotherapy, interferons, or retinoids (Hoppe et al, 1990; Olsen and Bunn, 1995; Diederer et al, 2003; Querfeld et al, 2005).

BENIGN CUTANEOUS DISORDERS SPECIFIC TO THE MALE GENITALIA

Angiokeratoma of Fordyce

Angiokeratomas of Fordyce are vascular ectasias of dermal blood vessels that may be visible on the penis and scrotum of adult men (Bechara et al, 2002). These lesions appear as 1- to 2-mm red or purple papules (Fig. 16-44A) and associated generalized scrotal redness may exist (Miller and James, 2002). This is usually a benign

condition without systemic manifestations, although it may rarely be a source of troublesome scrotal bleeding (Taniguchi et al, 1994; Hoekx and Wyndaele, 1998). Similar lesions can be observed in Fabry disease (Fig. 16-44B), which is a rare glycogen storage deficiency. Although treatment is usually unnecessary for angiokeratoma of Fordyce, several authors have reported success using erbium:YAG, Nd:YAG, KTP, and Argon laser photocoagulation in select cases (Occella et al, 1995; Bechara et al, 2004; Ozdemir et al, 2009).

Pearly Penile Papules

Pearly penile papules are white, dome-shaped or filiform, closely spaced small papules located on the glans penis (Fig. 16-44C). They are often arranged circumferentially at the corona. Pearly penile papules are common lesions found in up to 14% to 48% of young postpubertal adults, particularly if the penis is not circumcised (Rehbein, 1977; Khoo and Cheong, 1995; Sonnex and Dockerty, 1999). Although pearly penile papules may occasionally be misdiagnosed as condyloma, the available evidence does not support a role for HPV in causing pearly penile papules and no association with cervical intraepithelial neoplasia in female partners has been demonstrated (Hogewoning et al, 2003). Patients should be reassured that this is a benign condition that does not usually require treatment. If treatment is desired because of cosmetic concerns, local destruction with either the CO₂ laser or cryotherapy has been applied successfully (Ocampo-Candiani and Cueva-Rodriguez, 1996; Lane et al, 2002). Histologically,

these lesions are angiofibromas similar to the lesions seen on the face in tuberous sclerosis.

Zoon Balanitis

Zoon balanitis, also called plasma cell balanitis and balanitis plasmacellularis, occurs in uncircumcised men from the third decade onward (Pastar et al, 2004). Smooth, moist, erythematous, well-circumscribed plaques on the glans penis characterize the disease (Fig. 16-44D). Shallow erosions are often present (Yoganathan et al, 1994) and the lesions can be quite large (up to 2 cm in diameter) (Margolis, 2002). SCC and EPD must be excluded, typically by biopsy. Circumcision appears to be proof against development of the disease and can be performed to cure the majority of cases (Sonnex et al, 1982a; Ferrandiz and Ribera, 1984). For patients averse to circumcision, topical corticosteroids may provide symptomatic relief, and topical calcineurin inhibitors (tacrolimus or pimecrolimus) and laser therapy may also play a role in alleviation (Baldwin and Geronemus, 1989; Tang et al, 2001; Albertini et al, 2002; Retamar et al, 2003; Wojnarowska and Cooper, 2003; Rallis et al, 2007).

Figure 16-43. Mycosis fungoides (a cutaneous T-cell lymphoma) involving the buttocks. A shows the limited plaque stage, and B shows a more advanced case with plaques, patches, and tumors present. (From Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003.)

Sclerosing Lymphangitis

Nonvenereal sclerosing lymphangitis is a rare penile lesion consisting of an indurated, slightly tender cord involving the coronal sulcus and adjacent penile skin (Gharpuray and Tolat, 1991; Rosen and Hwang, 2003). It is usually flesh colored but may occasionally be red. A mechanism related to thrombosis of lymphatic vessels has been proposed. There is an association with vigorous sexual activity, and resolution usually occurs within several weeks (Sieunarine, 1987; Margolis, 2002). Although somewhat controversial, a search for concomitant gonococcal and nongonococcal urethritis may be advisable in these cases.

Median Raphe Cysts

Median raphe cysts occur in young men on the ventral aspect of the penis, most commonly near the glans (Stone, 2003). Although these cysts are believed to develop from aberrant urethral epithelium, they do not communicate with the urethra (Asarch et al, 1979). Treatment is accomplished by surgical removal.

Ectopic Sebaceous Glands

Ectopic sebaceous glands on the penile shaft may be visible as pin-sized, flesh-colored papular lesions that may be mistaken for verruca (Fig. 16-44E) (Margolis and Wein, 2002). There is no indication for treating these asymptomatic benign lesions and patient reassurance is sufficient.

COMMON MISCELLANEOUS CUTANEOUS DISORDERS

Skin Tag

Skin tags (acrochordons, fibroepithelial polyps) are soft, skin-colored, pedunculated lesions that can be present anywhere on the body but have a clear predilection for the neck, axillae, and inguinal folds. Although usually asymptomatic, these lesions may become painful secondary to local trauma or as a result of torsion and infarction in rare cases. These are common lesions, and up to 50% of all individuals may have at least one skin tag (Banik and Lubach, 1987). It is important to distinguish these lesions from the hamartomatous skin lesions (multiple fibrofolliculomas) associated with Birt-Hogg-Dube syndrome, which are histologically distinct from common skin tags (De la Torre et al, 1999). When skin tags cause either discomfort or cosmetic distress, they can easily be removed by snip excision and light electrocautery to the base to achieve hemostasis. When a large number of skin tags appear at a relatively young age (<40), there may be an association with both benign and malignant lower gastrointestinal tract polyposis, and gastroenterological referral for endoscopy should be considered (Piette et al, 1988).

Epidermoid Cysts

Epidermoid or epidermal-inclusion cysts are the most common cutaneous cysts, and these lesions can be found anywhere on the body including the genitalia. They are particularly common on the scrotum (Fig. 16-45E). The term “sebaceous cyst” should be avoided because the contents of these cysts are not sebaceous in origin (Stone, 2003). Although not painful at baseline,

Figure 16-44. Benign cutaneous disorders specific to the male genitalia. A, Angiokeratoma of Fordyce showing purple scrotal vascular malformations. B, Fabry disease: a glycogen storage deficiency with associated purple vascular malformations on the penile shaft. C, Pearly penile papules located on the corona of the glans penis. Philadelphia: Saunders; 1993; C and D, from Kortling GW. *Practical dermatology of the genital region*. Philadelphia: Saunders; 1981.)

Figure 16-45. Miscellaneous cutaneous disorders. A, Lentigo simplex involving the glans penis (penile melanosis). B, A compound melanocytic nevus in the inguinal crease. C, A dermatofibroma on the lower extremity. D, A characteristic seborrheic keratosis showing the “stuck-on” waxy appearance. E, Epidermoid cysts of the scrotum. F, Pedunculated neurofibroma. G, Vitiligo involving the penile shaft. (A, B, E, and G, From Korting GW. *Practical dermatology of the genital region*. Philadelphia: Saunders; 1981; C, from Bologna JL, Jorizzo JL, Rapini RP. *Dermatology*. Edinburgh: Mosby; 2003; D, from Habif TP. *Clinical dermatology*. Edinburgh: Mosby; 2004.)

rupture of the cyst wall can lead to a severe inflammatory reaction that is extremely painful. Definitive treatment requires surgical excision of the entire cyst wall to prevent cyst recurrence. Inflamed or superinfected epidermoid cysts may require incision and drainage and antibiotic therapy if there is adjacent cellulitis. Dystrophic calcification of scrotal epidermoid cysts may be a cause of scrotal calcinosis (Dare and Axelsen, 1988; Michl et al, 1994).

Seborrheic Keratosis

Seborrheic keratoses are very common beige to dark brown macules, plaques, and papules affecting individuals older than 30 years, and the incidence increases in frequency with advancing age. They are most common on the face, neck, and trunk although any body site except the palms, soles, and mucous membranes may be affected. The degree of pigmentation can vary significantly, and darker lesions may be confused with melanoma or warts (Pierson et al, 2003). These lesions have a waxy, “stuck-on” appearance (Fig. 16-45D) and patients may note that they drop off spontaneously and then regrow (Margolis, 2002). Treatment by shave excision or destruction with liquid nitrogen is usually performed for cosmetic reasons. An abrupt increase in the size and number of multiple seborrheic keratoses has been termed the Sign of Leser-Trelat and has been implicated as a cutaneous marker of occult internal malignancy (Chiba et al, 1996; Heaphy et al, 2000; Vielhauer et al, 2000; Ginarte et al, 2001).

Lentigo Simplex

Lentigo simplex is a condition characterized by the presence of brown-pigmented macules unrelated to sunlight exposure (Fig. 16-45A). These lesions can be found anywhere on the body including the mucous membranes and nail beds. In the genital area (benign genital lentiginosis), these lesions present commonly on the labia, vaginal introitus, perineum, and glans penis (penile melanosis). The lesions of lentigo simplex are usually smaller than those seen in melanocytic nevi. Although usually benign, the lesions of lentigo simplex may deserve biopsy evaluation in cases demonstrating atypical shape or coloration. When present in a discontinuous manner at multiple sites, the diagnosis of genital melanoma becomes less likely compared to the probability of benign genital lentiginosis. Finally, the combination of multiple pigmented lesions associated with intestinal polyposis should raise suspicion for Peutz-Jeghers syndrome.

Mole (Nevus)

A mole or nevus of the skin is composed of slightly altered melanocytes called “nevus cells” arranged in a cluster. The location of the cluster determines the type of nevus. Junctional nevi are located between the epidermis and dermis and are usually flat, tan to black in coloration, small (<5 mm), and sharply bordered (Margolis, 2002). Intradermal nevi have clusters within the dermis and are usually small (<5 mm), lighter in coloration, with sharp borders. Compound nevi have clusters in both locations and are usually darker and raised as a papule (Fig. 16-45B). As is the case for any pigmented lesion, marked irregularity in coloration or border, and rapid morphologic change with time, are indications for excisional biopsy.

Dermatofibroma

Dermatofibromas are small hyperpigmented nodules that occur most commonly on the lower extremities and occasionally on the genitalia (Fig. 16-45C). Pinching of these lesions causes a downward movement of the tumor (the so-called dimple sign) (Kamino and Pui, 2003). These are benign lesions with a characteristic histologic pattern of spindle-shaped fibroblasts and myofibroblasts arranged in fascicles. Treatment by surgical excision is usually unnecessary and may leave a scar that is cosmetically inferior to the original lesion (Kamino and Pui, 2003).

Neurofibroma

Neurofibromas are common tumors composed of neuromesenchymal tissue with residual nerve axons. They can be present anywhere on the body including the labia and scrotum (Yoshimura et al, 1990; Singh et al, 1992; Mishra et al, 2002; Kantarci et al, 2005). They are usually skin-colored, soft or rubbery nodular lesions, which may be pedunculated (Fig. 16-45F). Digital pressure on the lesion causes invagination or so-called button-holing (Habif, 2004). These can be solitary lesions or multiple, which should raise suspicion for neurofibromatosis or von Recklinghausen disease.

Capillary Hemangioma

Capillary hemangiomas are proliferations of blood vessels that are either present at birth or develop rapidly during the neonatal period. These lesions can involve the anogenital region, can lead to bleeding, or can cause obstruction of the urethra, vagina, or anus (Sharma et al, 1981; Roberts and Devine, 1983). The majority will involute during childhood or early adolescence (Margolis, 2002). An innovation in the treatment of very large, persistent, and/or obstructive hemangiomas is the systemic administration of propranolol; because this treatment is not without some risk, it should be initiated and supervised by a clinician experienced with this modality (Izadpanah et al, 2013).

Vitiligo

Vitiligo is an acquired autoimmune disorder of the skin, leading to depigmentation, affecting 0.5% to 2% of the global population (Ortonne, 2003). It might present at any age and the precise pathogenesis of vitiligo remains a topic of intense research effort. Large patches of skin become completely amelanotic. Although the skin appears white, it is otherwise completely normal. The borders with unaffected skin are usually sharp and well defined (Fig. 16-45G). This condition is particularly noticeable in darker skinned individuals and on body sites that are normally hyperpigmented. Vitiligo limited to the genitalia has been observed in less than 0.3% of the male population (Moss and Stevenson, 1981). Lesions have a tendency to enlarge circumferentially with time and might develop at sites of local trauma (Koebner phenomenon). Genital vitiligo must be differentiated from LS and postinflammatory hypopigmentation (Margolis, 2002). Treatments include temporary

KEY POINTS

- The diagnosis of cutaneous diseases of the external genitalia depends critically on a thorough history and physical examination. Extragenital findings may provide the key to diagnosis. The urologist should perform a thorough skin survey and should not focus solely on the area of affected genital skin.
- The side effects of topical corticosteroids are significant, both from systemic absorption and locally. Adverse effects may be worsened if these agents are applied under the foreskin, which may serve as an occlusive dressing. In general, when applied to genital skin, only low-potency topical corticosteroids should be used for short treatment courses.
- Cutaneous disorders of the external genitalia can be broken down into the general categories of allergic, papulosquamous, vesicobullous, ulcerative, infectious, neoplastic, and miscellaneous diseases.
- Histopathologic analysis of biopsy specimens plays an important role in differentiating cutaneous diseases with similar clinical features and in excluding malignancy.
- Local treatment modalities including the use of laser energy, photodynamic therapy, ultraviolet radiation, and cryotherapy are being applied successfully to a variety of genital cutaneous disorders and offer an alternative to surgical excision in some cases.

repigmentation with topical cosmetics, ultraviolet light exposure, PUVA therapy, and skin grafting. Use of the excimer laser to induce melanin production is particularly suited to the genitalia. **The diagnosis of vitiligo should prompt a screening for autoimmune thyroid disease.**

Genitourinary Tuberculosis

GENITOURINARY TUBERCULOSIS

Tuberculosis (TB) can affect any organ system of the body, including the genitourinary (GU) tract. Untreated, GU TB can lead to irreparable tissue damage with serious consequences such as renal failure and infertility, making it critical for clinicians to consider TB in the differential diagnosis of GU disorders. Described as the second “great imitator” (after syphilis) (Sievers, 1961), TB can mimic many other diseases and complicate the correct diagnosis and treatment of infected patients. As TB becomes less common in industrialized nations, the diagnosis of GU TB increasingly relies on clinical recognition and a high index of suspicion.

History

Genomic analyses suggest that *Mycobacterium tuberculosis* co-evolved with humans. Its early progenitor, *Mycobacterium prototuberculosis*, possibly infected early hominids more than 3 million years ago (Gutierrez et al, 2005). Bony lesions consistent with TB have been detected in a 500,000-year-old *Homo erectus* skeleton (Kappelman et al, 2008). The oldest microbiologic confirmation of *M. tuberculosis* infection in humans dates back to the Neolithic Period with use of DNA isolated from 9000-year-old skeletons of a woman and child found in a prehistoric site in the Eastern Mediterranean (Hershkovitz et al, 2008). Microscopic and molecular findings of tubercle bacilli have been documented in Egyptian mummies from circa 3000 BC (Zimmerman 1979; Nerlich et al, 1997). Descriptions of TB can be found in written records of civilizations from ancient East Asia, to New World cultures in the Americas, to Western Hemisphere societies such as the Greeks and Romans, and continuing into modern history (Daniel, 2006). It was not until the 18th and 19th centuries, however, that TB reached epidemic proportions and ravaged Europe and North America. “Consumption,” as it was known, was responsible for as many as 25% of deaths during the Industrial Age (Chalke, 1959). The turning point in the history of TB came on March 24, 1882, when Robert Koch famously presented to the scientific community the first successful isolation and identification of the tubercle bacillus (Sakula, 1982). In honor of Dr. Koch, March 24 has become World Tuberculosis Day.

Microbiology

Tuberculosis is caused by a group of closely related acid-fast bacteria referred to as the *Mycobacterium tuberculosis* complex (MTBC). The species that comprise the complex are *M. tuberculosis*, *Mycobacterium africanum*, *Mycobacterium bovis*, *Mycobacterium canettii*, *Mycobacterium microti*, *Mycobacterium caprae*, *Mycobacterium mungi*, *Mycobacterium orygis*, and *Mycobacterium pinnipedii* (Alexander et al, 2010; Coscolla et al, 2013). *M. tuberculosis* and *M. africanum* infect only humans, whereas the others infect humans and additional mammals. By far, the most frequently isolated species in human

Parasitic Infections of the Urogenital Tract

TB is *M. tuberculosis*. This species has become synonymous with TB and is often used to represent the entire complex. Although the mycobacterial species in the complex are clinically indistinguishable, drug susceptibility among them may differ. *M. bovis*, for example, has innate resistance to pyrazinamide, which is one of the first-line agents against *M. tuberculosis*.

Epidemiology

The World Health Organization (WHO) estimates that one third of the world’s population is infected with MTBC in its latent form. In 2012 there were 8.6 million new cases of active TB and 1.3 million deaths from TB worldwide, a decline that has continued since the year 2000. TB mortality has fallen by 45% since 1990 (WHO, 2013). However, new obstacles in TB control have also surfaced. These include medical conditions that promote resurgence of TB such as the human immunodeficiency virus (HIV) epidemic in sub-Saharan Africa and the rapid increase in obesity and diabetes worldwide. The appearance of multidrug and extensive drug resistance also compromises TB control.

In the United States, 9945 cases of active TB were reported in 2012 (3.2 per 100,000 persons). TB incidence in the United States has been steadily declining since its resurgence in the 1980s and its peak in 1992. In the United States, TB disproportionately affects the foreign-born. In 2012, the incidence among foreign-born individuals was 11 times higher than among U.S.-born persons (Centers for Disease Control and Prevention [CDC], 2013d).

The frequency of GU involvement among patients who develop TB varies significantly depending on the population studied. In developed countries, GU TB has been found in 2% to 10% of patients with pulmonary TB. In contrast, the frequency in developing countries approaches 15% to 20% (Figueiredo and Lucon, 2008). In the developing world, the GU tract is the second most common extrapulmonary site after lymph nodes (Wong et al, 2013). In the United States, GU TB is the third most common form after pleural and lymphatic TB and is found in 27% of extrapulmonary cases (Daher Ede et al, 2013). Approximately two thirds of those affected are men. GU TB is generally a disease of adults, although it has been reported in children as young as 2 years of age (Merchant et al, 2013a).

Transmission and Host Immune Response

The initial mode of entry of MTBC into the host is via inhalation of cough-generated infectious aerosols, although there are reported cases of direct inoculation of MTBC into soft tissues (Angus et al, 2001). When the bacilli reach the alveoli, they are phagocytosed by alveolar macrophages. In some persons, MTBC organisms are killed by the macrophages at this point and effectively cleared from the body. These persons do not develop infection nor an adaptive immune response (Walzl et al, 2011). In others, MTBC bacilli escape killing, begin to replicate within macrophages, and establish

infection. Up to 12 weeks may pass before a cellular immune response is detectable (Dannenberg, 1994), and before this development the tubercle bacilli can spread through the lymphatics to the hilar lymph nodes and ultimately through the bloodstream to seed distant organs.

The host attempts to contain MTBC infection by forming granulomas. Infected macrophages secrete inflammatory cytokines such as interleukin-6 (IL-6), IL-12, IL-1 β , and tumor necrosis factor- α (TNF- α) and recruit a variety of immune cells to surround them. Foamy macrophages, epithelioid cells, and multinucleated giant cells (Langhans cells) cluster to the center of the granuloma and are surrounded by a cuff of lymphocytes (Silva Miranda et al, 2012). Antigen processing and presentation lead to T-cell activation and the mounting of an adaptive cellular response against MTBC (Schluger and Rom, 1998). T cells secrete cytokines such as IL-2, TNF- α , and, most important, interferon- γ (IFN- γ) to maintain the granuloma and to induce killing of the infected macrophages and the infectious bacilli. When killing is not achieved, the granuloma can still successfully sequester viable tubercle bacilli, which stop replicating and become dormant. In 90% to 95% of persons, TB is controlled at this point and enters latency (Boom et al, 2003). Latent TB is marked by cicatrization and granuloma calcification. In fewer than 5% of infected persons the initial infection fails to be controlled and progresses within the year to active TB (primary progression). After latency is established, MTBC can resurface years later to cause reactivation TB. The process of reactivation is not well understood. The development of some conditions such as old age, renal failure, diabetes mellitus, malnutrition, HIV infection, and other causes of immune suppression shifts the balance between host and pathogen in favor of the pathogen. A series of events then occur that lead to renewed bacillary replication and release, granuloma caseation (the pathognomonic lesion of TB), and reactivation. The lifetime risk of reactivation TB is estimated at 5% to 10%, although the risk is higher in patients with the medical comorbidities mentioned previously. Treatment of patients with latent TB with isoniazid (INH) for 9 months can decrease the risk of reactivation by up to 90%.

Development of Genitourinary Disease

There are four means by which GU TB develops. The principal route is via hematogenous spread of MTBC. Clinical disease may occur soon after bacilli reach the GU system, or they may enter a period of latency before becoming clinically active (Figueiredo and Lucon, 2008; Patterson et al, 2012). Typically, GU TB becomes evident after a prolonged latency, ranging up to 46 years (Christensen, 1974; Narayana, 1982). Hematogenous seeding may localize to only the GU tract or may widely disseminate to multiple organ systems. The typical sites for GU seeding are the kidneys and epididymis. Other organs of the GU tract become infected via contiguous spread from these initial landing sites.

Ascending or retrograde infection through the urinary system is the second route of infection, albeit significantly less common than hematogenous spread. This is the case in GU TB after bladder irrigation with bacille Calmette-Guérin (BCG) for the treatment of bladder cancer. BCG is a live, attenuated vaccine derived from *M. bovis*, a member of the MTBC. Although rare, GU TB complicates 0.9% of patients receiving BCG irrigation (Lamm et al, 1992). Cases described include pyelonephritis, renal abscesses, ureteric obstruction, cystitis, prostatitis, and epididymo-orchitis (Squires et al, 1999; Demers and Pelsser, 2012; Parker and Kommu, 2013).

Rarely, TB can also reach the GU system via contiguous spread from other organ systems or direct inoculation. TB is one of the few infectious diseases that do not respect anatomic boundaries. Extension of TB from the spine and psoas to the kidneys has been described (Kothari et al, 2001). Similarly, gastrointestinal (GI) TB can extend into the GU tract to form enterorenal and enterovesical fistulae (Ney and Friedenber, 1981; Merchant et al, 2013a). Direct inoculation is exceedingly rare. Cases include autoinoculation of external genitalia from infected stool or urine, and person-to-person

genital inoculation after contact with infected genital or oral lesions (Angus et al, 2001).

Clinical Manifestations and Pathologic Features

Symptoms and signs of GU TB are often nonspecific. Patients are often treated for other bacterial infections (sometimes repeatedly) or are evaluated for possible malignancy before GU TB is entertained. Symptoms correlate with the severity and location of disease. Renal TB, for example, can be progressive and destructive but symptomatically silent until it extends into the bladder. In developed countries, where patients with TB tend to seek medical attention earlier in the disease process, 8.4% of GU TB patients are asymptomatic (Figueiredo and Lucon, 2008). The typical TB constitutional symptoms of fever, weight loss, night sweats, and malaise are present in fewer than 20% of patients (Simon et al, 1977). Up to 50% of patients with GU TB have only dysuria on presentation, 50% have storage symptoms, and 33% have hematuria and flank pain (Figueiredo and Lucon, 2008). Renal colic occurs in fewer than 10% of patients and corresponds to the passage of necrotic papillary tissue, clots, stones, and caseous phlegmon in patients with severe pyelonephritis (Simon et al, 1977; Eastwood et al, 2001). Typical laboratory findings include sterile pyuria and/or hematuria. This combination is found in more than 90% of GU TB patients in developing countries.

Kidney

The kidney is the most common site of GU TB (Wong et al, 2013). Renal infection is progressive and highly destructive over time. The pathologic findings in the kidney vary greatly depending on disease severity.

The most insidious lesions are found in patients with pulmonary TB and renal failure, with or without pyuria, who have no changes visible on imaging of the GU tract. In these patients, kidney biopsies reveal TB-induced granulomatous interstitial nephritis (Ram et al, 2011). Renal histology shows granulomas, which are sometimes caseating. In some patients, treatment reverses the associated renal insufficiency (Eastwood et al, 2001). Other microscopic changes in the kidney include glomerulonephritis from immune complex deposition or amyloidosis secondary to TB (Sun et al, 2012). In these patients, the kidneys are collateral damage of pulmonary or systemic disease.

When renal infection is the outcome of widely disseminated TB in multiple organ systems, hematogenous spread of high numbers of bacilli leads to innumerable small (3-mm), pale clumps of granulomas that look like scattered millet seeds on gross pathologic examination of the kidney. This form of disseminated TB is known as *miliary TB* and carries a high mortality. In the kidney, the "milia" can be found studding the renal cortex and medulla and do not usually affect renal function (Eastwood et al, 2001).

In more localized infection of the kidney, tubercle bacilli become lodged first in the periglomerular capillaries. Granulomas form in the renal parenchyma and coalesce. When they caseate, cavities with necrotic material form. These can result in frank abscesses, chronic pyelonephritis, and parenchymal and papillary necrosis. Sinus tracts may emerge along the flanks (Bhatt and Lodha, 2012; Patterson et al, 2012). Examination findings at this stage can include costovertebral angle tenderness (Gokce et al, 2002). As infection advances, the calyces become inflamed and eventually calcify, resulting in calyceal distortion, dilatation, and stenosis (Merchant et al, 2013a).

With enough disease progression, the kidney becomes nonfunctional, a process called *autonephrectomy* (Teo and Wee, 2011). This complication is present in up to 33% of patients with GU TB. There are two types of autonephrectomy. The first is the caseo-cavernous type, in which viable tissue is replaced with granulomas and cavities filled with inflammatory exudate. This type of autonephrectomy occurs both with and without calcification. The second type is fibrotic, with severe scarring and calcification resulting in a shrunken kidney (Fischmann, 1951).

End-stage renal failure develops in approximately 7% of patients (Figueiredo and Lucon, 2008). Chronic inflammation may lead to squamous metaplasia in the renal pelvis that persists after treatment, posing a risk for squamous cell carcinoma (Byrd et al, 1976).

Ureter

TB in the ureters occurs via descent of infection from the kidneys. As bacilli pass in the urine through the ureter, granulomas can form along the walls. Infected calculi can also descend and lodge in the ureters. The ensuing inflammation leads to scarring and strictures, commonly in the distal end of the ureter at the vesicoureteral junction (Patterson et al, 2012). Strictures can also occur throughout the ureter in a “pan-ureteral” fashion leading to a “beaded corkscrew” appearance (Wong et al, 2013). When ureters are distorted from scarring, both obstruction and urinary reflux can develop (Eastwood et al, 2001). Urinary obstruction resulting from strictures is an important cause of renal failure in GU TB (Carl and Stark, 1997).

Bladder

Descending infection to the bladder usually begins near the ureteral orifices and spreads along the lymphatics to other areas. Similar to TB in the ureters, bacilli implant in the urothelium and cause a patchy cystitis. Ulcerations may develop in areas where large granulomas coalesce. The dome of the bladder is the most affected, whereas the trigone and neck usually remain normal. Mucosal inflammation, friability, and hematuria all follow (Wong et al, 2013). After approximately a year of chronic inflammation and mucosal scarring, bladder contracture develops (Singh et al, 2013). Urinary frequency, urgency, pain, and dysuria become prominent when bladder capacity shrinks to less than 100 mL. The severely contracted “thimble” bladder typically has a capacity of less than 20 mL. Bladder contraction is a late complication of GU TB and is more common in the developing world (12% vs. 4% of GU cases in developed countries), where diagnosis occurs after disease is more advanced (Figueiredo and Lucon, 2008).

Epididymis, Vas Deferens, Testes, and Scrotum

The epididymis, the second most common GU site of hematogenous seeding after the kidney, is involved in 10% to 55% of GU TB patients. Infection is bilateral in 34%. The disease initially affects the more vascular globus minor. Granulomas in the epididymal epithelium elicit chronic inflammation leading to fibrous narrowing and obliteration of the lumen. With disease progression, large caseous granulomas result in a nodular epididymis. On examination, the epididymis may appear swollen or hardened (Fraietta et al, 2003). In granulomas may adhere to the overlying skin and ulcerate, and in up to 50% of patients a tuberculous sinus tract develops on the posterior surface of the scrotum (Ferreira et al, 2011). After the infection spreads to the vas deferens, it becomes thickened and beaded on examination as a result of nodular scarring (Kulchavenya et al, 2012).

Isolated epididymis or testicular infections are rare but have been described (Kho and Chan, 2012; Shenoy et al, 2012). More commonly, epididymal TB extends into the testes. Granulomas form within the seminiferous tubular epithelium as well as in the connective tissue of the testis. Eventually, normal tissue becomes replaced with granulomatous tissue and fibrosis. The hardened masses that develop mimic testicular tumors. Approximately 5% of patients develop hydrocele.

Prostate and Seminal Vesicles

The prostate is infected via either hematogenous spread or urinary contamination. With hematogenous spread, prostatic lesions can be found in the periphery with sparing of the urethra. Disease then remains asymptomatic and progresses to calcification and gland hardening. Infection via the urinary route often involves the urethra and manifests more like bacterial prostatitis. Prostatic nodules or

fluctuation might be palpated on examination. TB should be suspected in patients with chronic prostatitis that persists despite antibiotics. Quinolones used to treat routine bacterial prostatitis are also active against MTBC. However, the shorter courses used for bacterial prostatitis are not sufficient for TB prostatitis, and the symptoms will not resolve or will quickly recur. Prostatic abscesses are rare but do occur, particularly in acquired immunodeficiency syndrome (AIDS) patients (Figueiredo and Lucon, 2008).

TB of the seminal vesicles may cause infertility, which can be the first symptom of GU TB (Lübbe et al, 1996). The bacilli reach the seminal vesicles through the vas deferens in patients with TB of the testis or epididymis, or through the urethra and ejaculatory ducts in patients with TB of the kidneys, bladder, or prostate. Granulomas develop in the walls of the seminal vesicles, and the lumen may be filled by caseation. Eventually calcification ensues. Patients may have low-volume ejaculate, oligospermia, azoospermia, or hematospermia. TB can rarely cause seminal vesicle abscesses (Eastham et al, 1999). Physical examination might reveal enlarged seminal vesicles with earlier detection, or hardened nodules with advanced disease.

Penis and Urethra

The urethra appears somewhat resistant to TB infection and is involved in only 1.9% to 4.5% of GU TB patients. It is typically associated with prostate infection and can manifest with urethroscrotal fistulae. Isolated urethral TB is very rare but has been reported (Bouchikhi et al, 2013). Similarly, primary TB in the penis is exceedingly rare. Penile lesions begin on the skin as an inflamed papule or a keratotic plaque (also known as *lupus vulgaris*). The lesions then ulcerate and spread to the cavernous tissue. Pea-sized nodules can be felt in the cavernous bodies and urethra corresponding to coalescing granulomas. These can be painless and hard, similar to malignancy. When fibrosis develops, the penis can become distorted (Angus et al, 2001; Gupta et al, 2008b; Kar and Kar, 2012).

Orificial TB, a rapidly necrotic form of penile TB, has also been reported (Ramesh and Vasanthi, 1989). It has been described in immunocompromised or severely debilitated patients. It arises from autoinoculation of the penile skin with infected stool or urine from the patient, or rarely from hematogenous or lymphatic spread (Wilkinson et al, 2010). Painful ulcers coated with pseudomembrane appear and can erode into deeper structures (Chen et al, 2000). Orificial TB is a presentation of very advanced and severe TB elsewhere in the GU or GI tract and carries a poor prognosis.

An exceedingly rare form of penile TB is papulonecrotic tuberculid (PNT) (Dandale et al, 2013). This is a cutaneous manifestation of TB on the glans penis and can occur in other skin areas as well. PNT of the penis has been described in Japan, South Africa, and India. The tuberculids are red papules that erupt on the skin, ulcerate, and undergo varioliform scarring. Unlike primary TB of the penis, these ulcers can be painless and do not contain tubercle bacilli. The tuberculids are hypersensitivity reactions to MTBC antigens that were disseminated to the skin from other infectious foci, and as such they are culture negative and typically polymerase chain reaction (PCR) negative. Histology is often inconclusive, as mature granulomas are not always seen. The recurrent lesions are easily confused with syphilis, Behçet disease, recurrent herpes simplex, balanitis, and squamous cell carcinoma. Recognizing this entity is the first step in diagnosis, and response to empirical TB treatment despite negative cultures confirms it.

Diagnosis

In developed countries, the primary goal of the diagnostic workup is isolation of MTBC in culture for drug susceptibility testing. In the right clinical context, tissue samples demonstrating caseating granulomas can support a diagnosis of TB when cultures or DNA test results are negative. Absent those, diagnosis of patients with GU TB relies on the constellation of consistent clinical findings in a patient with probable exposure and response to empirical medical treatment. Because up to 20% of GU TB occurs concurrently with

pulmonary TB (Figueiredo and Lucon, 2008), it is useful to also assess for the presence of pulmonary disease.

Culture

The current gold standard for the diagnosis of GU TB is urine acid-fast bacilli (AFB) culture. First-void urine is the best sample because urine is the most concentrated at that time. Three to five urine samples on consecutive days should be collected for maximum yield. These should be cultured immediately after collection because prolonged exposure to urine acidity can retard mycobacterial growth (American Thoracic Society, 2000a). The sensitivity of urine AFB cultures is as high as 80% when done in this manner. In real-world practice, however, sensitivity can be as low as 10% (Abbara and Davidson, 2011). Ziehl-Neelsen stains can be done on the urine as well, but the sensitivity is less than 50%. In addition, any tissue obtained from biopsy or surgery should also be cultured.

Mycobacterium tuberculosis complex has traditionally been cultured on solid, egg-based, Löwenstein-Jensen (LJ) medium. This method is laborious and time-consuming; usually 4 to 6 weeks are required before growth of MTBC can be detected. LJ remains the medium of choice in developing countries because it is the least expensive and requires no specialized equipment. In developed countries, urine is cultured on more expensive, agar-based, transparent, solid media, such as Middlebrook 7H10. With this medium, colonies can be visualized approximately 1 week earlier than with LJ media. Liquid-based detection systems such as the BACTEC Mycobacteria Growth Indicator Tube (MGIT) are also used in the developed world. The MGIT is a fully automated system that uses fluorescence quenching to detect mycobacterial growth in liquid media in as little as 10 days. Current guidelines recommend culturing on at least one solid medium concurrently with the liquid system to maximize yield (American Thoracic Society, 2000a). Other available detection methods include semiautomated systems that use radiometric liquid culture. Antibiotic susceptibility can be tested using any of the culture methods described earlier. Typically, susceptibility to first-line TB drugs is tested "in house" with use of the MGIT instrument. Susceptibility testing for second-line TB drugs is generally performed only at reference laboratories.

Nucleic Acid Amplification Tests

Several amplification tests have been developed to speed the detection of MTBC, providing results within 1 to 2 days. This can also aid detection in cases with low bacillary load, in which culture might fail to isolate the organisms. The tests have reported sensitivities ranging from 87% to 96% when compared with culture. However, nonsputum specimens such as urine contain natural inhibitors that interfere with the DNA or RNA amplification process, potentially resulting in false-negative test results (Moussa et al, 2000; Chawla et al, 2012; Mehta et al, 2012). The sensitivity of PCR tests for GU TB also depends on the type of sequence amplification used. Assays using the MTBC repetitive IS6110 insertion sequence perform better than those amplifying 16S-rRNA (Moussa et al, 2000).

In general, nucleic acid amplification tests (NAATs) are frequently underused in developed countries because culture is necessary for drug susceptibility testing. In developing countries, the cost and the need for expensive equipment have been the obstacles. Unlike cultures, NAATs cannot be used to monitor response to treatment because nucleic acids are shed from dead organisms and test results can remain positive despite adequate treatment (American Thoracic Society, 2000a).

In 2010, WHO enthusiastically endorsed the newest TB PCR assay on the market, the GeneXpert MTB/RIF. The system provides a self-contained platform that automates sputum processing, DNA extraction, and amplification in less than 2 hours. It simultaneously detects the presence of MTBC and rifampin resistance. Because more than 90% of rifampin-resistant strains are also INH-resistant, rifampin resistance serves as a surrogate marker for multidrug-resistant tuberculosis (MDR-TB) (Ioannidis et al, 2011). The assay

has been most studied with sputum samples and appears to have sensitivity similar to culture. Its use for GU TB is still being evaluated. In a small study of extrapulmonary TB that included 91 urine samples (only five of which were culture positive), the GeneXpert was 100% sensitive and 98.6% specific (Hillemann et al, 2011).

Histopathology

Histopathology shows findings consistent with TB in 38.3% of GU TB cases in developed countries and 21.9% of cases globally. Because urine cultures are sometimes negative, tissue biopsy can aid the diagnosis of GU TB (Kulchavenya et al, 2013). Although mycobacteria are often not seen, the finding of caseating granulomas in the appropriate clinical context can help establish a diagnosis of GU TB.

Screening Tests

The tuberculin skin test (TST) and interferon-gamma release assays (IGRAs) do not differentiate between latent and active TB. They have limited usefulness in the diagnosis of active disease, although they are widely used and are approved by the U.S. Food and Drug Administration (FDA) for this purpose. A positive test result cannot rule in active TB, and a negative test result cannot rule it out. The ideal use for these tests is in the screening of individuals for the presence of latent TB infection. However, in the absence of other positive test results, the use of these screening tests can sometimes help sway the physician toward making a diagnosis of active TB disease.

Tuberculin Skin Test, Purified Protein Derivative, Mantoux Test. The TST evaluates the presence of an existing cellular immune response to MTBC antigens, which should be present in persons who have been infected. Tuberculin is a sterile suspension of protein extracted from cultures of *M. tuberculosis* and is injected intradermally into the volar aspect of the forearm. After 48 to 72 hours, delayed-type hypersensitivity will cause induration at the site of injection in those with prior immune priming. The CDC guidelines for interpretation of a positive test result depend on the risk factors of the patient. Three distinct cut-points for positivity have been defined according to risk. For persons with recent contact with a patient with TB, with fibrotic changes on chest radiographs that are consistent with prior TB, or who are immunosuppressed, 5 mm of induration or more is positive. For recent immigrants from high-prevalence countries, residents of or workers in high-risk institutions, injection drug users, and persons with medical comorbidities that increase risk of active TB, 10 mm of induration or more is positive. For the general public, 15 mm or more is positive (Box 17-1) (American Thoracic Society, 2000b).

Although initial training of personnel both in test placement and interpretation is necessary, the TST has many advantages. It is cheap, does not require a laboratory, and is easy to perform. The main disadvantage is that the TST is not specific for MTBC. Vaccination with BCG and infection with nontuberculous mycobacteria may elicit a positive reaction. In addition, the TST requires a second visit from the patient for test reading, which can be difficult to ensure. False-negative results can occur in 10% to 25% of persons with active TB (Huebner et al, 1993). In one study, the TST result was positive in 85% to 95% of patients with GU TB (Figueiredo and Lucon, 2008).

Interferon-Gamma Release Assays. IGRAs are blood tests that measure the level of IFN- γ (a surrogate of cellular immune reactivity) produced in response to MTBC-specific antigens, akin to an in vitro MTBC-specific TST. Persons infected with MTBC have circulating T cells that quickly recognize MTBC antigens and secrete IFN- γ on re-exposure. The antigens used in IGRAs are absent from all BCG strains and most nontuberculous mycobacteria, and thus exposure to these organisms does not result in a positive IGRA result. Results are available after 24 hours.

There are two IGRAs available in the United States: the QuantiFERON-TB Gold In-Tube test (QFT-GIT) and the T-SPOT.TB test. The QFT-GIT is simpler to run, whereas the T-SPOT.TB

BOX 17-1 Guidelines for Determining a Positive Tuberculin Skin Test Reaction**INDURATION ≥ 5 mm**

- HIV-positive persons
- Recent contacts of patient with active TB
- Fibrotic changes on chest radiograph consistent with prior TB
- Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of >15 mg/day prednisone for longer than 1 month, or TNF- α antagonists)

INDURATION ≥ 10 mm

- Recent arrivals (<5 yr) from high-prevalence countries
- Injection drug users
- Residents and employees of high-risk congregate settings: prisons and jails, nursing homes and other health care facilities, residential facilities for AIDS patients, and homeless shelters
- Mycobacteriology laboratory personnel
- Persons with clinical conditions that put them at high risk: silicosis, diabetes mellitus, chronic renal failure, some hematologic disorders (e.g., leukemias and lymphomas), other specific malignancies (e.g., carcinoma of the head or neck and lung), weight loss exceeding 10% of ideal body weight, gastrectomy, jejunoileal bypass
- Children younger than 4 years or infants, children, and adolescents exposed to adults in high-risk categories

INDURATION ≥ 15 mm

- Persons with no risk factors for TB; however, targeted skin testing programs should only be conducted among high-risk groups

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; TB, tuberculosis; TNF, tumor necrosis factor.

Modified from Diagnostic standards and classification of tuberculosis in adults and children. This official statement of the American Thoracic Society and the Centers for Disease Control and Prevention was adopted by the ATS Board of Directors, July 1999. This statement was endorsed by the Council of the Infectious Disease Society of America, September 1999. *Am J Respir Crit Care Med* 2000;161(4 Pt. 1):1376–95; and Centers for Disease Control and Prevention. Tuberculosis (TB) fact sheets, <http://www.cdc.gov/tb/publications/factsheets/testing/skintesting.htm>; September 1, 2012 [accessed 09.02.15].

IGRA requires more steps. In the QFT-GIT, whole blood is collected in three specialized test tubes, one containing the MTBC antigens ESAT-6, CFP-10, and TB7.7, and two controls (negative and positive). The blood is incubated directly in the collection tubes for 16 to 24 hours. Plasma is then separated and IFN- γ is measured using enzyme-linked immunosorbent assay (ELISA). Test results are read as positive, negative, or indeterminate, based on the level of IFN- γ produced in relation to the negative and positive controls. In the T-SPOT.TB assay, peripheral blood mononuclear cells are separated from whole blood and then incubated with ESAT-6 and CFP-10 in wells coated with antibodies that capture IFN- γ . Enzyme-linked immunospot (ELISPOT) assay is used to detect an increase in the number of cells (appearing as spots in each test well) that secrete IFN- γ in relation to a negative control. Spots are manually counted, and the test result is read as positive, negative, or borderline. Despite the increased difficulty of performing T-SPOT.TB over QFT-GIT, it is the more sensitive test. Pooled studies estimate a sensitivity of 83% for QFT-GIT and 91% for T-SPOT, versus 89% for TST in cases of culture-confirmed TB (Mazurek et al, 2010).

Figure 17-1. Kidney-ureter-bladder radiographic view in a patient with left renal tuberculosis with associated calcifications.

Radiography

GU TB generates a wide spectrum of imaging findings. The test of choice depends on disease location and should be driven by symptoms and other clinical data. Imaging is often the first test that indicates TB is the cause of a GU disorder.

Plain Radiography. The kidney-ureter-bladder (KUB) radiograph will frequently demonstrate calcifications caused by TB, which are present in more than 50% of patients (Merchant et al, 2013a). Initial renal lesions may appear as faint punctate calcifications within the parenchyma. As TB progresses, the KUB film may show globular calcifications that correspond to a tubercular mass (Fig. 17-1). Papillary necrosis appears as triangular ringlike calcifications in the collecting system. With fibrotic autonephrectomy, the KUB radiograph shows a small, shrunken, calcified “cement” or “putty” kidney, in which calcific rims outline the individual renal lobes; this lobar pattern is pathognomonic for end-stage renal TB.

A plain radiograph can also demonstrate renal and ureteral TB-infected calculi. Stones may take strange shapes as they form in a deformed and fibrosed renal pelvis. A stone in the shape of an upward arrowhead may indicate a renal pelvis that has been “hiked up” by contraction from scarring.

The KUB film can also show ureteral calcifications, which are characteristically intraluminal as opposed to the mural calcifications of schistosomiasis. Bladder wall calcifications are not very common except in late cases of bladder contraction. Calcifications of the prostate and seminal vesicles are seen in 10% of patients. Plain film findings suggestive of TB may be seen in surrounding tissues as well, appearing as erosions of the vertebral bodies or calcifications in cold abscesses of the psoas muscle (Teo and Wee, 2011; Merchant et al, 2013a).

Intravenous Urography. Intravenous urography (IVU) is the gold standard for imaging early renal TB. Initial erosive changes of the urothelium appear as loss of sharpness and edge irregularities (Figueiredo and Lucon, 2008). Calyceal erosions have a moth-eaten appearance (Patterson et al, 2012). Filling defects may be seen, caused by tuberculomas rupturing into the calyx or by papillary

necrosis. IVU can demonstrate medullary cavities that communicate with the collecting system. When a calyx or infundibulum is stenosed, contrast excretion by the renal parenchyma may fail, creating a “phantom calyx” in the location where the calyx should be visible (Eastwood et al, 2001). Ureteral TB can manifest as a rigid, calcified, straightened, pipestem ureter that is tubular and lacks normal peristaltic activity on IVU. The ureter may also take on the appearance of a beaded corkscrew as a result of nodular fibrosis along the entire ureter. The pipestem and corkscrew findings are highly suggestive of TB, particularly when seen concurrently with either kidney or bladder abnormalities. IVU can also detect nonfunctional kidneys resulting from autonephrectomy, as well as a fibrosed, contracted bladder (Fig. 17-2). On occasion, perinephric abscess might be suggested, particularly if there is restriction of renal movement with breathing, or ureteral displacement on IVU.

The most common findings on IVU, however, are obstructive changes resulting from scarring and distortion of the collecting system: calyceal obliteration, infundibular narrowing, hydrocalycosis, segmental or total hydronephrosis, and hydroureter (Figs. 17-3 and 17-4). Calyceal dilatation and distortion will present a typical cloverleaf pattern on film (Carl and Stark, 1997). Ureterovesical junction obstruction is caused by tuberculous cystitis or strictures of the distal third of the ureter (Fig. 17-5). The finding of a “hiked-up” renal pelvis, with sharp angulation of the ureteropelvic junction (UPJ), is known as “Kerr’s kink” (Merchant et al, 2013a).

Computed Tomography with Urography. Computed tomography (CT) with urography is the most frequently used modality for imaging TB in developed countries, where it has largely replaced IVU (Merchant et al, 2013b). High-end multidetector scanners can detect lesions as small as 3 to 4 mm. With the administration of intravenous contrast, CT can assess kidney function during different phases of excretion. Similar to KUB and IVU, CT reveals calcifications, scarring, and signs of obstruction (Fig. 17-6). CT is more sensitive than KUB in detecting calcifications and thickening of the collecting ducts. It is particularly useful in evaluating patients with complicated and extensive TB. Perinephric and psoas abscesses can

be seen, as well as any pathology in lymph nodes, vertebrae, spleen, or liver. Pathology in the prostate and seminal vesicles can also be visualized, including enlargement, necrosis, cavitations and abscesses, and calcifications.

CT does have disadvantages. CT is less sensitive for detecting the minimal urothelial thickening, subtle papillary necrosis, and other changes of early renal TB, for which IVU is still the preferred study. In addition, CT imparts a higher radiation dose than IVU.

Figure 17-3. Occluded calyx.

Figure 17-2. The cystogram portion of an intravenous pyelogram in a patient with left renal tuberculosis. Note the contracted left side of the bladder that is secondary to fibrosis from the tuberculosis.

Figure 17-4. Severe calyceal and parenchymal destruction.

Figure 17-5. Stricture at the distal left ureter.

Figure 17-6. Computed tomography scan after oral contrast medium in a patient with bilateral renal tuberculosis. The right kidney is hydronephrotic secondary to infundibular stenosis but has retained good function. The left kidney is an end-stage nonfunctioning atrophic kidney with calcification.

Retrograde Pyelography and Antegrade Pyelography. Both retrograde and antegrade pyelography, with either percutaneously or endoscopically administered contrast, have been replaced by CT urography. However, when IVU or CT cannot be done because of renal insufficiency or contrast allergy, these modalities can be helpful in delineating the distortions in GU anatomy. In addition, these tests can be used in conjunction with IVU to determine whether cavitations are obstructive or nonobstructive, and whether they are in communication with the urinary collecting system or not (Merchant et al, 2013b).

Ultrasonography

Ultrasonography (US) has a limited role in the diagnosis of GU TB because findings are generally nonspecific and visualization is not as clear as with CT. It is useful in pediatric or pregnant patients because of the lack of radiation exposure. US is also less expensive than CT. US can be used to evaluate the testes, epididymis, and, with transrectal US, the prostate and seminal vesicles, which will appear thickened. US can also locate abscesses or cavities in the kidney. Cystic lesions with septations suggest chronic infection (Wong et al, 2013). Focal calcifications appear as highly echogenic areas with distal shadowing. Restriction of renal movement during breathing suggests a perinephric or psoas abscess. Like CT, US can provide concurrent information about the abdomen, such as the presence of ascites, lymphadenopathy, or omental caking. A primary use of US in GU TB is to follow hydronephrosis in patients who are receiving medical treatment because fibrosis during healing can worsen urinary obstruction.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is not commonly used in the workup of GU TB because of the many other imaging modalities available (Merchant et al, 2013b). Similar to US, it can be useful in pediatric or pregnant patients to avoid exposure to radiation. MRI can detect a single granuloma. Small lesions are hypointense on both T1 and T2 images. Larger lesions have central hyperintensity on T2 images because of the increased cellularity at the center of the granuloma. Larger TB lesions can mimic malignancy, and it is not always possible to differentiate the two.

A magnetic resonance urogram (MRU) can be more sensitive than IVU in showing urothelial thickening and caliectasis. The addition of diffusion-weighted imaging (DWI) can help distinguish hydronephrosis from pyonephrosis. Various techniques have been explored with MRI to study TB, including cine MRU and dynamic MRU, which can evaluate ureteral peristalsis. MRI with DWI can be used to monitor renal fibrosis. Apparent diffusion coefficients (ADCs) decrease with fibrosis and can be used to gauge the stage of TB, including the effect of treatment. Caution should be exercised with use of gadolinium in renal failure patients because of the risk of development of nephrogenic systemic fibrosis.

Cystoscopy and Ureteroscopy

Endoscopy plays a limited role in the diagnosis of TB. Although it allows direct visualization of lesions, findings can be nonspecific. They include local hyperemia, mucosal erosion, ulceration, granulomatous masses, and irregularity of the ureteral orifices. Ulcerative lesions may mimic malignancy. A "golf-hole" ureteric orifice is suggestive of TB, and, when found, upper tract imaging or endoscopy should be performed (Fig. 17-7). Biopsies should be performed when possible, especially if malignancy is a possibility. Although a positive urine culture for MTBC is sufficient for diagnosis, results may not be available quickly enough. Furthermore, in those with negative urine cultures, bladder biopsy can be 19% to 52% sensitive for TB (Figueiredo and Lucon, 2008).

Treatment

Before the development of antimicrobials, treatment of TB relied primarily on rest and nourishment in sanatoria; and in those with severe GU disease, extirpative surgery was the best hope for cure. With the development of streptomycin in 1944, followed by INH in 1952 and the rifamycins in 1957, medical treatment with antituberculous drugs replaced sanatoria and surgical procedures (Daniel, 2006). Today, most TB patients can be treated medically and in the ambulatory setting, even those with MDR-TB. Surgery now serves primarily to establish a diagnosis or as an adjunct to antibiotics in advanced cases (Abbara and Davidson, 2011).

D, Acute tuberculous ulcer. E, Tuberculous golf-hole ureter. F, Tuberculous golf-hole ureter, severely withdrawn. G, Healed tuberculous lesion. H, Acute tuberculous cystitis with ulceration.

Medical Therapy

Successful medical treatment of TB requires multiple drugs for several reasons (CDC, 2003). First, the tubercle bacilli exist in different microenvironments within the host. These apply different pressures on the organism and cause it to exhibit

different metabolic needs and replication speeds. The drugs vary in their activity against MTBC; some are bactericidal, whereas others are only bacteriostatic. Some drugs work best on rapidly replicating bacteria, whereas others are more effective against dormant bacilli. The drugs also penetrate differently into various tissues and perform optimally at different pHs. In addition,

TABLE 17-1 First-Line Antituberculous Drugs

DRUG/FORMULATION	ADULT DOSAGE (DAILY) ¹	ADULT DOSAGE (INTERMITTENT) ²	MAIN ADVERSE EFFECTS
Isoniazid (INH) ³ 100-mg, 300-mg tabs 50-mg/5-mL syrup 100-mg/mL injection	5 mg/kg (max 300 mg)	15 mg/kg (max 900 mg) 3 times/wk	Hepatic toxicity, peripheral neuropathy
Rifampin (Rifadin, Rimactane) ⁴ 150-mg, 300-mg caps 600-mg injection powder	10 mg/kg (max 600 mg)	10 mg/kg (max 600 mg) 3 times/wk	Hepatic toxicity, flulike syndrome, pruritus, drug interactions
Rifabutin (Mycobutin) ⁵ 150-mg caps	5 mg/kg (max 300 mg)	5 mg/kg (max 300 mg) 3 times/wk	Hepatic toxicity, flulike syndrome, uveitis, neutropenia, drug interactions
Rifapentine (Priftin) ⁶ 150-mg tabs		10 mg/kg/wk PO (max 600 mg) Continuation phase only in very select patients	Similar to rifampin
Pyrazinamide 500-mg tabs	40-55 kg: 1000 mg 56-75 kg: 1500 mg 76-90 kg: 2000 mg	3 times/wk: 40-55 kg: 1500 mg 56-75 kg: 2500 mg 76-90 kg: 3000 mg	Arthralgias, hepatic toxicity, pruritus, rash, hyperuricemia, gastrointestinal upset
Ethambutol (Myambutol) 100-mg, 400-mg tabs	40-55 kg: 800 mg 56-75 kg: 1200 mg 76-90 kg: 1600 mg	3 times/wk: 40-55 kg: 1200 mg 56-75 kg: 2000 mg 76-90 kg: 2400 mg	Decreased red-green color discrimination, decreased visual acuity, optic neuritis

1. Or 5 times/wk directly observed therapy (DOT).

2. Intermittent therapy (administered by DOT) only during the continuation phase of therapy. The World Health Organization (WHO) no longer recommends dosage intervals less frequent than 3 times/wk.

3. Pyridoxine 25 to 50 mg should be given to prevent neuropathy in malnourished or pregnant patients and those with human immunodeficiency (HIV) infection, renal failure, thyroid disease, alcoholism, or diabetes.

4. In general, cannot be taken by HIV-infected persons taking protease inhibitors or certain non-nucleoside reverse-transcriptase inhibitors (NNRTIs).

5. When taken with efavirenz, the rifabutin dose is increased to 450 mg/day or 600 mg 3 times/wk. When taken with fosamprenavir, nelfinavir or indinavir, the rifabutin dose is 150 mg/day or 300 mg 3 times/wk. With ritonavir, atazanavir, or ritonavir combined with other protease inhibitors, the rifabutin dose is 150 mg every other day or 3 times/wk; some experts believe this dose to be subtherapeutic and recommend 150 mg daily or 300 mg 3 times/wk with close monitoring for rifabutin toxicity, particularly uveitis.

6. Rifapentine is contraindicated in HIV-positive persons, in persons with cavitary pulmonary disease, and in persons with extrapulmonary tuberculosis. Use of once-weekly rifapentine is not advocated by WHO.

From Drugs for tuberculosis. Treat Guidel Med Lett 2012;10(116):29-36; and modified by Centers for Disease Control and Prevention (CDC). Treatment of tuberculosis, American Thoracic Society, CDC, and Infectious Diseases Society of America. MMWR Recomm Rep 2003;52(RR-11):1-77.

multiple drug therapy prevents the emergence of drug-resistant strains.

Combination therapy with first-line antituberculous drugs achieves the best cure rates in the shortest time frame (Table 17-1). Treatment should start with these—namely, INH, rifampin, pyrazinamide, and ethambutol. Before the start of treatment, baseline measurements should include blood counts and liver and kidney function tests. Patients should also be tested for HIV and, when appropriate, hepatitis B and C. Medical therapy should be tailored according to drug susceptibility data when available. Directly observed therapy (DOT) should be employed to ensure medication adherence and minimize the likelihood of development of drug-resistant strains.

Second-line agents are reserved for patients in whom first-line agents fail or who experience side effects from first-line agents, and for cases of drug resistance. Second-line agents vary in tolerability and ease of administration (Table 17-2). Recent drugs added to the second-line agents are the fluoroquinolones and linezolid (Lee et al, 2012), both of which were developed to treat other bacterial infections, and bedaquiline—the first new drug in 40 years specifically developed for TB. It was fast-tracked by the FDA and approved for use on December 28, 2012 after completion of only phase 2b

studies. Currently, it is approved only as part of combination therapy for drug-resistant pulmonary TB (CDC, 2013b).

Genitourinary TB can be successfully treated with the standard short-course regimen of 6 months of first-line antituberculous drugs (CDC, 2003). Treatment begins with an intensive phase of 2 months of daily INH, rifampin, and pyrazinamide, followed by a continuation phase of 4 months of INH and rifampin given daily, or alternatively thrice weekly. Twice-weekly administration during the continuation phase is no longer recommended (WHO, 2010). Pyridoxine (vitamin B₆) administration minimizes the risk of INH-induced peripheral neuropathy. Ethambutol is added at the beginning of treatment pending drug susceptibilities and is discontinued if the strain is found to be susceptible to the other first-line drugs. First-line drugs reach high concentrations in the urine and work well in acidic environments. The intensive phase of treatment targets rapidly multiplying bacteria, whereas the continuation phase attempts to eradicate slow, sporadic multipliers and persistent bacteria.

Although 6 months is the duration of standard short-course therapy, clinical scenarios regularly arise that require prolongation of treatment. Both the type of clinical disease present and the antituberculous drugs used affect duration of treatment (CDC, 2003).

TABLE 17-2 Second-Line Antituberculous Drugs

DRUG/FORMULATION	ADULT DOSAGE (DAILY) ¹	MAIN ADVERSE EFFECTS
Streptomycin ²	15 mg/kg IM, IV (max 1 g)	Vestibular and auditory toxicity, renal damage
Capreomycin (Capastat) ²	15 mg/kg IM, IV (max 1 g)	Auditory and vestibular toxicity, renal damage, electrolyte imbalance
Kanamycin (Kantrex and others) ²	15 mg/kg IM, IV (max 1 g)	Ototoxicity, renal damage
Amikacin (Amikin and others) ²	15 mg/kg IM, IV (max 1 g)	Ototoxicity, renal damage
Cycloserine (Seromycin) ³	10-15 mg/kg in 2 doses (max 500 mg bid) PO	Psychiatric symptoms, seizures
Ethionamide (Trecator-SC)	15-20 mg/kg in 1 or 2 doses (max 500 mg bid) PO	Gastrointestinal and hepatic toxicity, hypothyroidism, optic neuritis, neurotoxicity
Levofloxacin (Levaquin)	500-1000 mg PO, IV	Gastrointestinal toxicity, central nervous system effects, rash, dysglycemia, QT prolongation, tendinitis or tendon rupture
Moxifloxacin (Avelox)	400 mg PO, IV	Gastrointestinal toxicity, central nervous system effects, rash, dysglycemia, QT prolongation, tendinitis or tendon rupture
Aminosalicylic acid (PAS; Paser)	8-12 g in 2 or 3 doses PO	Gastrointestinal disturbance, hepatitis, hypothyroidism
Linezolid (Zyvox)	600 mg PO bid	Bone marrow suppression, peripheral and optic neuropathy, hepatic toxicity
Bedaquiline (Sirturo) ⁴	400 mg PO	Headache, nausea, arthralgias, QT prolongation, hepatic toxicity

1. Dosage may need to be adjusted for patients with renal impairment.

2. In general, given 5 to 7 times/wk (15 mg/kg, or a maximum of 1 g per dose) for an initial 2 to 4 months, and then (if needed) 3 times/wk (20 to 30 mg/kg, or a maximum of 1.5 g per dose). Administration less frequently than 3 times/wk is no longer recommended. For patients older than 59 years, dose is reduced to 10 mg/kg (max 750 mg per dose). Dose should be decreased if renal function is diminished.

3. Some authorities recommend pyridoxine 50 mg for every 250 mg of cycloserine to decrease the incidence of adverse neurologic effects.

4. Bedaquiline is given at 400 mg orally with food, daily for 2 weeks, then 200 mg orally 3 times/wk.

From Drugs for tuberculosis. Treat Guidel Med Lett 2012;10(116):29-36; and modified by Centers for Disease Control and Prevention (CDC). Treatment of tuberculosis, American Thoracic Society, CDC, and Infectious Diseases Society of America. MMWR Recomm Rep 2003;52(RR-11):1-77; Lee M, Lee J, Carroll MW, et al. Linezolid for treatment of chronic extensively drug-resistant tuberculosis. N Engl J Med 2012;367(16):1508-18; and CDC. Provisional CDC guidelines for the use and safety monitoring of bedaquiline fumarate (Sirturo) for the treatment of multidrug-resistant tuberculosis. MMWR Recomm Rep 2013;62(RR-09):1-12.

For example, treatment for at least 9 months is recommended for extensive pockets of infection, concurrent smear-positive cavitary pulmonary disease, central nervous system involvement, or a delay in positive cultures converting to negative. If the patient is unable to take pyrazinamide for at least 2 months, because of either side effects or drug resistance, the duration of therapy should also be 9 months or longer. Some clinicians recommend 12 months of therapy for GU TB because of high relapse rates of up to 22% when therapy is given for only 6 months (Gokalp et al, 1990). Because of the complexities that often arise with regimen choice, drug interactions, and side effects, any deviation from standard short-course therapy should be discussed with specialists experienced in treating TB.

During therapy, liver enzymes should be monitored monthly in those with preexisting liver disease because all first-line agents except ethambutol can cause hepatic toxicity that can be reversed with drug discontinuation (CDC, 2003). Patients should be advised to abstain from alcohol and other hepatotoxic drugs. Although treatment is, in general, well tolerated, severe hepatic injury has occurred. Visual acuity and red-green color perception also should be monitored in patients taking ethambutol. Close follow-up of patients is necessary, not only to monitor for side effects, but also because renal lesions may worsen with drug treatment. The healing process is sometimes accompanied by new fibrosis, which can worsen urinary obstruction and bladder contraction (Psihramis and Donahoe, 1986). Steroids may help in the management of these patients (see later). Surgical intervention to relieve worsening or newly developed obstruction might be necessary.

Corticosteroids. The role of adjunctive corticosteroids for the treatment of active TB still needs to be fully elucidated. The

anti-inflammatory effects of corticosteroids are thought to prevent an unchecked host immune response from causing excessive tissue destruction and scarring. They are strongly recommended for TB meningitis and TB pericarditis, and they are sometimes used in patients with severe pulmonary TB, when antibiotic treatment leads to a paradoxical worsening of symptoms (Breen et al, 2004). Steroids have also been used in a few patients with GU TB to prevent ureteral strictures and bladder contraction, but these situations are anecdotal and no clinical trials have been conducted. A recent review and meta-analysis of published clinical trials of corticosteroid use in pulmonary, meningeal, pleural, pericardial, and peritoneal TB showed that regardless of which organ system was affected, steroids reduced mortality by 17% (Critchley et al, 2013).

Surgical Therapy

About 55% of patients with GU TB will require surgical management during the course of their disease (Wong et al, 2013). Intervention is more frequent as disease advances. Surgical procedures are performed to relieve urinary obstruction and drain infected material, to remove nonworking infected kidneys in cases resisting cure, to improve medically resistant hypertension secondary to a functionally excluded kidney, or to reconstruct the urinary tract. Currently, more than half of operations performed for TB are reconstructive (Gupta et al, 2008b). The optimal timing of surgery is 4 to 6 weeks after the initiation of medical therapy. This delay allows active inflammation to subside, the bacillary load to decrease, and lesions to stabilize.

Procedures to Relieve Obstruction. Prompt relief of obstruction is emergently required in cases of uremia or sepsis. Bilateral

obstruction or unilateral obstruction of a functionally solitary kidney is often the cause of renal failure. Early ureteral stenting or percutaneous nephrostomy (PCN) for tuberculous ureteral strictures limits the loss of renal function and increases the opportunity for later reconstructive surgery (Shin et al, 2002). Temporary and immediate drainage of obstruction is recommended, preferably by retrograde ureteric stenting. An indwelling double-J stent can be placed until the patient's condition has been optimized. Retrograde placement is successful in 41% of cases (Ramanathan et al, 1998). When this is not technically feasible, an antegrade, internalized or externalized ureteral stent is placed via percutaneous puncture of the obstructed kidney. If that also fails, a PCN is left in place until definitive management. Because strictures and fibrous scars may be present, more than one PCN may be necessary (Carl and Stark, 1997). PCN must be followed by correction of the cause of obstruction. A tuberculous cutaneous fistula can develop if the PCN is simply removed, although this is less likely to develop with effective concurrent medical therapy. If the kidney is unsalvageable, a nephrectomy may become necessary. High-contrast injection pressures during stent and PCN placement should be avoided to prevent possible dissemination of infection (Salem, 2008).

Nephrectomy. Organ preservation is the fundamental goal in surgical management of GU TB. However, total nephrectomy is considered in two settings. The first is the patient with a nonfunctional kidney and recalcitrant or recurrent TB despite optimal medical therapy. After nephrectomy of the infected kidney, relapse rates of less than 1% have been reported following short-course medical treatment (Figueiredo and Lucon, 2008). The second setting in which nephrectomy is considered is the patient with a nonfunctional kidney and medically resistant hypertension. Nephrectomy improves hypertension in 65% of patients (Flechner and Gow, 1980). Overall, nephrectomy is performed in 27% of GU TB patients, and the frequency is similar between developed and developing countries (Figueiredo and Lucon, 2008).

Because of the extensive fibrosis often present, the traditional approach to the kidney is through an oblique retroperitoneal incision that can be extended dorsally or ventrally as needed. In rare patients the perinephric fat may appear to have granulomatous masses or caseous cavities. These should be removed with the specimen. Individual ligation of the renal artery and vein is preferred to limit risk of late arteriovenous fistula. The ureters are usually not taken out concurrently. Care must be taken to minimize disruption of the surrounding lymphatics and to avoid entering the pleural or peritoneal space during the procedure.

More recently, laparoscopic nephrectomy has gained popularity (Lee et al, 2002; Hemal, 2011) despite concerns that extensive fibrosis associated with TB would render a laparoscopic approach suboptimal. Several investigators have reported good outcomes and suggest that it should be the preferred approach because of decreased blood loss and more rapid patient recovery (Chibber et al, 2005; Zhang et al, 2005; Gupta et al, 2008a). In experienced hands, laparoscopic nephrectomy for renal TB is a somewhat longer procedure than when it is done for other reasons, but in one study the procedure took only half an hour longer on average (Lee et al, 2002).

Ureteropelvic and Ureteral Surgery. Strictures of the UPJ and ureter may be temporarily stented to allow improvement of renal function before definitive management. Upper ureteric and mid-ureteric strictures are rare and may be amenable to endourologic treatment. Lower ureteric strictures are more common and often require open surgical intervention. The length and degree of the stricture, whether it can be passed by a guidewire or not, vascular supply to the lesion, and renal function are important factors to be considered in the management of patients (Kim et al, 1993).

Endoscopic Management. Tuberculous ureteric strictures are characterized by mucosal ischemia and dense fibrosis. Hence, success rates for endoscopic management of strictures from other causes may not necessarily apply to TB strictures. In general, short strictures with residual lumens in patients with good renal function yield the best outcome. Strictures forming during medical treatment and managed by early stenting (double-J placement) can stabilize and require no further treatment (Shin et al, 2002). Balloon dilatation

by retrograde or antegrade access has been described for TB strictures of the ureter, UPJ, ureterovesical junction, and calyceal infundibula (Murphy et al, 1982; Kim et al, 1993). A stent is often placed after dilatation. Because of high failure rates, repeated procedures are often needed.

Follow-up imaging (US or IVU) of all patients with ureteric strictures is needed, especially those managed endoscopically, because some strictures will worsen during the healing process as a result of fibrosis and cicatrization. Corticosteroids may be added if deterioration is detected. Failure to improve or progression after 6 weeks of medical treatment is an indication for open surgical management.

Open Surgical Options. Long, complex strictures require open surgical repair. Because of fibrosis, loss of elasticity, and reduced vascularity, mobilization of structures may be difficult. Repair of UPJ scarring is more challenging in patients with TB than in those with congenital stenosis. Dismembered pyeloplasty is feasible for extrarenal pelvis with short-segment scarring. Nondismembered (flap) pyeloplasty is preferred for longer strictures but may not be feasible because of excessive scarring of the pelvis. When anatomic reconstruction is not possible, ureterocalicostomy (anastomosis of the ureter to the lower pole calyx) is an option. The renal capsule should be preserved to cover the lower pole of the kidney. If not enough capsule is available, omentum can be used to avoid stenosis at the calicoureteral anastomosis (Carl and Stark, 1997).

Upper and middle ureteric strictures can be managed by excision of the diseased segment, and, with adequate mobilization, a primary tension-free ureteroureterostomy can be performed. Alternatively, lysis of adhesions and intubation (Davis intubated ureterotomy) may be done. Lower ureter strictures requiring surgery are best managed by complete excision of the entire affected ureteric segment back to healthy ureteric mucosa that has good blood supply. The resultant gap is bridged with a tension-free, well-vascularized anastomosis to healthy bladder (ureteroneocystostomy). Various procedures exist to bring the bladder closer to the ureteric end. Simple mobilization of the lateral attachments of the bladder on the contralateral side, accompanied by division of the superior vesical artery, may provide 2 to 3 cm of length to bridge a small gap. In patients with good bladder capacity, a psoas hitch may also be performed. Care must be taken to avoid the genitofemoral and femoral nerves when placing these sutures. A well-performed psoas hitch can bridge a gap of up to 5 cm. A Boari flap is another method of bridging a longer gap of 10 to 15 cm and may be performed in combination with a psoas hitch (Sankari, 2007). It is important to note that a poorly executed Boari flap can compromise bladder capacity. Contracted bladders from TB cystitis may not have sufficient surface area and elasticity to allow flap creation. Finally, ileal interposition (ileal ureteric replacement) can be done in patients with multiple or recurrent strictures when the native ureter is no longer an adequate conduit (Goel and Dalela, 2008).

Bladder Surgery. Augmentation cystoplasty and bladder substitution are options in the management of the tuberculous contracted bladder. First described in the 19th century for a tuberculous contracted bladder, augmentation is indicated when frequency, nocturia, urgency, pain, and hematuria become intolerable—typically when bladder capacity is less than 100 mL (Gupta et al, 2008b). For severely contracted bladders, ileocecum or sigmoid segments are most suitable. When only half the bladder is diseased, ileum is often used. Other segments used in augmentation include stomach and cecum. The general rules of incorporating the bowel into the urinary tract apply, such as thoroughly evaluating renal function, reconfiguring a low-pressure reservoir (de Figueiredo et al, 2006), performing patient education, and conducting long-term follow-up. Thimble bladders with capacity less than 20 mL are best managed by orthotopic bladder substitution (Hemal and Aron, 1999). Complications of either bladder augmentation or substitution include mucus production, electrolyte derangements, and secondary bacterial infection.

Urethra 1 Procedures. Bladder neck contracture is best managed endoscopically by transurethral incision of the contracture. Urethral

strictures are also managed endoscopically and often require repeated procedures. Tuberculous urethral fistulae are treated by initiation of medical therapy and suprapubic bladder drainage. Delayed reconstruction is preferred. Drainage of a seminal vesicle tuberculous cavity into the bladder by cold knife incision has been reported (Dewani et al, 2006).

Genital Surgery. Extirpative surgery for genital TB is considered only for patients in whom medical therapy has failed. When the epididymis is infected with sparing of the testis, every effort should be made to perform an epididymectomy alone without orchiectomy. Preserving testicular blood supply is important during dissection of the epididymis. Initiating dissection at the globus minor after ligation of the vas facilitates excision. If the testes are infected, a scrotal orchiectomy can be done. Involvement of the vas deferens by TB is usually distal to the external ring, and ligation at the level of the ring is possible and sufficient.

Monitoring for Tuberculosis Relapse

Even with optimized treatment, as with any infection, TB can relapse in 2% to 6% of pulmonary TB patients, particularly within the first year after treatment (CDC, 2003). A second, longer, or different drug course is then required. GU TB patients may relapse at a higher rate than pulmonary TB patients, in 6.3% to 22% of cases, even after 12 months of medical therapy (Figueiredo and Lucon, 2008). The extensively diseased kidney can contain innumerable foci of tubercle bacilli. Difficulty in achieving complete sterilization of all foci with antituberculous drugs may be the reason for the higher relapse rate. Viable bacilli have been identified in the kidneys even after 9 months of treatment (Figueiredo and Lucon, 2008). In all patients with recurrent TB, extra effort should be exerted to isolate the organism for drug susceptibility testing. Pulmonary TB patients are usually followed for 2 years after completing treatment; for GU TB patients, some investigators have recommended 10 years of follow-up, because the average time of relapse was 5.3 years (Gokce et al, 2002).

Management of Genitourinary Tuberculosis in Special Situations

Each of the special situations that follow require special handling of the antituberculous regimen because of side effects, interactions, and drug toxicities. Expert advice should be sought from infectious diseases specialists or physicians experienced in the treatment of TB.

Multidrug-Resistant and Extensively Drug-Resistant Tuberculosis

Persons with MTBC strains that are resistant to both INH and rifampin (the two most important first-line agents) have MDR-TB. Worldwide, approximately 3.7% of newly diagnosed patients and 20% of previously treated patients have MDR-TB (CDC, 2013b). Treatment is complicated by the need to use regimens longer than 18 months. The cure rate is 50% to 60% compared with 94% to 97% in patients with drug-susceptible TB (CDC, 2009). Among patients with MDR-TB, 9% have additional drug resistance, qualifying as extensively drug-resistant tuberculosis (XDR-TB) (CDC, 2013b). XDR-TB is resistant to INH, rifampin, any fluoroquinolone, and at least one of the injectable second-line aminoglycosides (amikacin, kanamycin, or capreomycin). XDR-TB is exceedingly difficult to cure, with complicated regimens involving five or six drugs for 2 years or more. As a result, the cure rate of patients with XDR-TB is only 30% to 50% (CDC, 2013c).

Pregnancy and Lactation

Women of childbearing age should be advised to avoid pregnancy while being treated for active TB. If the diagnosis is discovered

during pregnancy, prompt therapy should be initiated because the risk to the fetus from TB outweighs the risk of adverse drug effects. Treatment consists of INH, ethambutol, rifampin, and pyridoxine, for 9 months. Pyrazinamide is avoided because the effects on the fetus are unknown. Postpartum, women may breastfeed their infants because drug concentrations in breast milk are too low to cause toxicity.

Human Immunodeficiency Virus Infection

HIV infection increases the risk of active TB 30-fold. With HIV and TB coinfection, each disease accelerates the other. All TB patients should be tested for HIV. Among HIV-positive persons in the world, almost 25% of deaths are due to TB (WHO, 2013). This is reminiscent of TB mortality rates in 18th- and 19th-century Europe.

Extrapulmonary, and consequently, GU TB may be more common in HIV-positive patients. In a small study in India, GU TB was found postmortem in 49% of AIDS patients (Lanjewar et al, 1999). In HIV-positive patients, GU TB can be more disseminated, with more lymph node enlargement and bilateral renal disease. Usually, less caseation, necrosis, and fibrosis are present because a competent immune system is necessary for the vigorous inflammatory process that leads to fibrosis and scarring. As a result, among patients with GU TB, stenosis of the collecting system occurs less frequently (12.5% vs. 93.8% in HIV-negative persons), and there is a lower incidence of bladder contracture (12.5% vs. 65.3% in HIV-negative persons with GU TB) (Figueiredo et al, 2009). Despite the lower incidence of obstructive cicatricial lesions, GU TB in HIV-positive persons is associated with high mortality.

TB treatment in HIV-positive patients should not be delayed. Treatment guidelines are similar to those for persons without HIV infection. Short-course chemotherapy for 6 months is effective, and 9 months of treatment is no longer routinely recommended. Instead, duration of treatment is determined by the usual factors: disease location and severity, drugs tolerated, and response. During the continuation phase of therapy, however, HIV-positive patients should undergo daily or thrice-weekly administration, and nothing less frequent. Drug interactions with antiretrovirals can be complex and need to be considered. The rifamycins (rifampin and to a lesser degree rifabutin) may decrease serum levels of antivirals to suboptimal levels. Dose increases may be needed as a result (Kaplan et al, 2009).

Renal Transplant Recipients

Renal allograft TB is rare. Infection usually occurs in kidney transplant patients within 6 months of transplantation but can occur as late as 7 years after. The shorter interval from infection to presentation may be a result of the immunosuppression required for the graft or of preexisting TB in the donor kidney. Because patients are seen very early in the disease process, no changes are usually visible on imaging. Furthermore, the immunosuppression prevents much of the pathology that is part of the natural course of GU TB. Diagnosis is difficult because many of the symptoms and findings of GU TB are absent. Fever is the usual presenting symptom. Urinary symptoms are present in only 20% of cases (el-Agroudy et al, 2003). Chest x-ray findings are abnormal but not specific in 55% of patients. Regardless of chest x-ray findings, 56% of patients have positive sputum cultures. In one study, urine AFB culture was positive in 100% of patients (Dowdy et al, 2001). Many patients are diagnosed after graft nephrectomy with histopathology (Lorimer et al, 1999).

Treatment is complicated by drug interactions between the rifamycins and the immunosuppressive drugs, necessitating frequent monitoring of serum drug levels and dosage adjustments. Rifamycin-free regimens are possible but lengthen the duration of treatment to at least 12 to 18 months. Complications in transplant patients include graft rejection, disseminated TB, and death in up to 36% of patients (Dowdy et al, 2001).

PARASITIC INFECTIONS OF THE UROGENITAL TRACT

A number of parasitic infections affect the urogenital tract. Although urologists practicing in nonendemic areas may encounter patients with urogenital parasitic infections only rarely, it is nevertheless critical for physicians to understand these diseases to facilitate appropriate diagnosis and therapy of affected individuals. Parasitic infections relevant to urology include urogenital schistosomiasis, filariasis, amebiasis, enterobiasis, and echinococcosis.

Schistosomiasis

More than 200 million people globally are infected by *Schistosoma* species. The three species of primary medical importance are *Schistosoma mansoni* (found primarily in Africa, the Arabian Peninsula, and South America), *Schistosoma japonicum* (China and Southeast Asia), and *Schistosoma haematobium* (Africa and the Arabian Peninsula). Whereas *S. mansoni* and *S. japonicum* primarily affect the liver and GI tract, *S. haematobium* infection primarily affects the GU tract and is the focus of this chapter. Urogenital schistosomiasis is a disease featuring a complex parasite life cycle, multifaceted human disease, and close ecologic links to the environment. *S. haematobium* likely has co-evolved with humans and nonhuman

primates for millennia; as a result, even ancient civilizations realized the constellation of signs and symptoms associated with urogenital schistosomiasis.

History

The presence of schistosome antigens in Egyptian mummies (circa 3500 BCE), including more recent mummies with confirmed *S. haematobium* eggs in tissues (Deelder et al, 1990), confirms that urogenital schistosomiasis has been with *Homo sapiens* for millennia. Indeed, the Egyptians recognized this infection and named it "A-a disease," which was depicted hieroglyphically by a penis dripping with bloody urine (Hanafy et al, 1974; Shokeir and Hussein, 1999). Later, the German pathologist Theodor Bilharz, performing autopsies in Cairo in 1852, found worms in mesenteric veins and linked them to eggs found in human urine and stool.

Biology and Life Cycle

Human infection is initiated by the penetration of *S. haematobium* cercariae through (even intact) skin that is in contact with infested fresh water (Fig. 17-8). The average life span of cercariae is 1 day.

Figure 17-8. Life cycle of a schistosome. UTIs, urinary tract infections. (From King CH. Schistosomiasis. In: Guerrant RL, Walker DH, Weller PF, editors. Tropical infectious diseases, principles, pathogens, and practice. 2nd ed. Philadelphia: Churchill Livingstone; 2006. p. 1341-8.)

Penetration success rates fall off quickly within hours of cercarial shedding from the intermediate snail host (King, 2006).

After penetration, schistosomes transform from free-living cercariae into obligate parasites called *schistosomulae*, by first shedding their tails over approximately 90 to 120 minutes and then undergoing a series of structural changes (Melo and Pereira, 1985). The transformed schistosomulae migrate to the lungs via the bloodstream or lymphatics, and then the liver via the venous circulation (Wilson, 2009). Migration out of the skin and into the lungs takes several weeks (Rheinberg et al, 1998; Wilson, 2009).

The juvenile schistosomes then arrive at the liver sinusoids via the venous circulation, where they begin blood feeding. Soon thereafter, the now-mature worms preferentially migrate to the venous plexus of the bladder and other pelvic organs, where they live an average of 3 to 5 years. The developmental period from cercaria to adult worm ranges from 80 to 110 days. After worm pairing, males clasp the females in a ventral groove termed the *gynecophoric canal*, using their muscular bodies to help females pump host blood into their mouths and secreting chemical signals to stimulate oviposition (Gupta and Basch, 1987).

Eggs are laid by adult female worms in the pelvic venous circulation. Human schistosomes are very fecund, with egg-laying rates of hundreds to thousands of eggs per female per day. *S. haematobium* eggs are ovoid, measuring approximately 140 μm long and featuring a terminal spine (Loker, 1983; Ratard and Greer, 1991) (Fig. 17-9). Eggs must penetrate the endothelium to reach the lumen of bladder to exit via the urinary stream, reach fresh water, and hatch to become miracidia. Some *S. haematobium* eggs are also excreted into the feces after expulsion from the intestinal wall. It is estimated that less than half of the eggs produced are successfully excreted in urine. The rest are retained in the body where the immune response causes significant pathology.

Eggs can survive approximately 20 days as long as they remain wet. On contact with fresh water and light, the eggs hatch, releasing miracidia, which are the larval stage of the parasite. The ciliated miracidia of *S. haematobium* infect intermediate host snails of the

Bulinus genus. *Bulinus* snails prefer slow-flowing freshwater habitats and are able to withstand low-oxygen conditions.

The typical life span of a miracidium is 6 hours. If during this brief period a *Bulinus* snail is encountered, the miracidia will penetrate the snail tissue and form a primary sporocyst. After several days, 20 to 40 daughter sporocysts are generated by the primary sporocyst. These eventually mature into 200 to 400 cercariae (per sporocyst), which are released back into water. The prepatent period (the time between initial penetration of the snail by a miracidium and release of the first cercariae) varies with water temperature; at temperatures below 15°C or greater than 35°C, no cercariae are shed (Pflüger et al, 1984).

Epidemiology

The geographic distribution of urogenital schistosomiasis is dependent on the tropical conditions required by *S. haematobium* and its specific snail hosts. Consequently, *S. haematobium* is endemic throughout much of sub-Saharan Africa and in portions of North Africa and the Middle East. Approximately 112 million people worldwide have urogenital schistosomiasis (van der Werf et al, 2003). Up to 150,000 people die annually from *S. haematobium*-induced obstructive renal failure alone. It has been calculated that in a 2-week period in 2003, 70 million and 32 million individuals in sub-Saharan Africa experienced *S. haematobium*-induced hematuria and dysuria (respectively), and that major bladder wall pathology and major hydronephrosis were present in 18 and 10 million people (respectively) (van der Werf et al, 2003).

For individuals, the risk of contracting urogenital schistosomiasis is primarily driven by the nature and length of contact with contaminated fresh water. Rural women and children can be exposed during domestic chores when they use *S. haematobium*-infested ponds, rivers, and lakes as their water supply (e.g., for laundry and dishwashing). Children may also be infected while playing and swimming in infested water. Men and women can be exposed during freshwater fishing, washing cars, and working in agricultural areas with high-water-intensity crops such as rice and sugar cane (Hunter et al, 1993). In endemic areas, schistosomiasis prevalence is usually highly focal because of the localized nature of water-dependent transmission.

On a regional level, land-use patterns and ecologic changes can lead to a higher burden of schistosomiasis in some areas, sometimes even resulting in outbreaks. For instance, it has been recognized for at least a century that building dams and irrigation schemes can increase schistosomiasis transmission by creating year-round, slow-flowing, freshwater habitats for the intermediate snail hosts and by promoting increased human population density associated with expanded agriculture. Accordingly, data from Africa consistently show that populations living near dams and irrigation schemes have a greater risk of contracting schistosomiasis compared with populations living distantly from these schemes (Steinmann et al, 2006).

In the 1930s after the construction of the Aswan Low Dam in Egypt, which led to a conversion from ancient, flood-based irrigation to perennial irrigation, the prevalence of schistosomiasis increased from less than 11% to more than 75% in some regions (Hunter et al, 1993). Similar findings occurred after the construction of the Aswan High Dam in Egypt during the 1960s (Malek, 1975) and the Diama Dam in West Africa during the 1980s (Malek, 1975; Talla et al, 1990).

Communities with poor sanitation and a lack of access to clean, running water are generally at highest risk of harboring schistosomiasis (WHO, 2014b). Children are disproportionately affected, with the highest parasite loads occurring in those aged 5 to 15 (Anderson and May, 1992). It is unclear whether this age distribution results from higher exposure among children or a higher inherent susceptibility (Woolhouse et al, 1991).

Schistosomiasis is associated with poverty for a number of reasons. First, the aquatic snails that harbor the larval forms of schistosomes are distributed within tropical and subtropical developing countries, whereas they are not present in developed nations

Figure 17-9. Micrograph of *S. haematobium* eggs. Note the characteristic terminal spines of the eggs. (From Ray D, Nelson TA, Fu CL, et al. Transcriptional profiling of the bladder in urogenital schistosomiasis reveals pathways of inflammatory fibrosis and urothelial compromise. *PLoS Negl Trop Dis* 2012; 6(11):e1912.)

in temperate zones. Second, inadequate sanitation exacerbates the schistosomiasis problem because the schistosome life cycle requires an influx of eggs from human excreta into surface fresh waters. Moreover, prolonged contact with surface fresh water is promoted by lack of safe water supplies, leading to higher risk of infection (Soares Magalhães et al, 2011). Finally, schistosomiasis contributes to the perpetuation of poverty. Chronic infection adversely affects childhood growth, development, and learning, as well as worker productivity (Bonds et al, 2010).

Pathogenesis and Pathology

Cercarial skin penetration is facilitated by secreted molecules such as proteases, which initiate the cellular and humoral responses to schistosome infection (Curwen et al, 2006). However, likely as a result of the parasite strategy of modulating the host immune response from the moment of first contact, brief cercarial penetration does not typically induce an immune response beyond localized skin inflammation (Jenkins et al, 2005). Regardless, repeated exposure to schistosomes can lead to hypersensitization and the development of a maculopapular rash.

During subsequent maturation into adult worms, schistosomes begin to generate a double lipid bilayer outer surface (the tegument), which allows them to evade an immunopathologic response and remain in the host for years, facilitating chronic infection. As the survival of the worm within the host depends significantly on the tegument, numerous mechanisms are employed for immune evasion, including host antigenic mimicry, continual membrane turnover, immunomodulatory proteins and proteases, host-evading biophysical properties of the tegument, and modulation of expression of surface antigens (Abath and Werkhauser, 1996).

Because it is difficult to study the natural pathogenesis of egg-associated disease in humans, much of our knowledge stems from autopsy studies and animal models. In contrast to the relatively silent immune response to worms, the main immunopathologic responses raised against *S. haematobium* are triggered by oviposition in the walls of the bladder and other pelvic organs. With heavy worm burdens, egg deposition in the pelvic organs leads to granuloma development and eventual fibrosis, often obstructing the flow of blood or urine. Granulomas are characterized by a mixed leukocytic infiltration, including eosinophils, plasma cells, and lymphocytes. Because of continuous oviposition, all stages of granulomas are simultaneously present in individuals with chronic infection. Composite, coalescing granulomas are common, secondary to *S. haematobium* egg deposition in clusters. Grossly, granulomatous inflammation can form bulky, hyperemic, and polypoid masses projecting into the bladder lumen (Fig. 17-10). Other factors that have been shown to influence the host immune response and resulting disease severity include host genetics, in utero sensitization to parasitic antigens, and coinfection by other microbes or parasites (Pearce and MacDonald, 2002; Eriksson et al, 2007; Grant et al, 2011). *S. haematobium* eggs appear to rapidly induce bladder expression of type 2 inflammation-associated genes and suppress transcription of urothelial barrier function-related genes (Fu et al, 2012; Ray et al, 2012). These findings suggest that the parasite and human host may share the goal of expelling eggs from the bladder wall, across a temporarily lowered urothelial barrier, and out into the urinary stream.

Although *S. haematobium* has tropism for the pelvic organs, some oviposition occurs in the portal tract. As a result, portal hypertension occurs when eggs are swept into the liver, clog presinusoidal capillaries, induce granuloma formation, and consequently block the hepatic vasculature. Alternatively, embolized eggs can cause granulomatous and fibrotic portal areas and the dilation of collateral portosystemic shunts, permitting the lodging of eggs in these vessels and the formation of pipestem fibrosis (Symmer fibrosis) (Aubry et al, 1980). Hepatosplenomegaly is one clinical manifestation of Symmer fibrosis, although susceptibility to its development depends largely on the variability of individual immune responses. In addition to portal involvement, migration of worm pairs to the pulmonary vessels can result in oviposition in the lungs. In general,

Figure 17-10. Intravenous urogram in an Egyptian boy shows scalloping of the bladder and right lower ureter by schistosomal polypoid lesions.

pulmonary schistosomiasis develops only in very severe cases of infection and when pathogenesis in other organs (i.e., pelvic) has already occurred (Borgstein, 1964). When pulmonary oviposition occurs, eggs may obstruct the lung vasculature and lead to pulmonary fibrosis, pulmonary hypertension, and/or cor pulmonale (Bedford et al, 1946).

Naturally acquired immunity to urogenital schistosomiasis exists; some individuals maintain negative urine egg counts for at least 5 years despite never having received anthelmintics in the face of continual exposure to *S. haematobium* (McManus and Loukas, 2008). The resistance of these individuals to reinfection has been attributed to the involvement of both a T-helper type 1 (Th1) and a Th2 cytokine response, whereas chronically infected individuals exclusively mount a Th2 response (McManus and Loukas, 2008). In some individuals the activity of potentially protective immunoglobulin E (IgE) antibodies may be blocked by IgG4 antibodies generated against worm and egg antigens, possibly hampering the development of protective immunity to schistosomiasis (Hagan et al, 1991).

Because levels of IgE antibodies to worm antigens have been observed to increase with age (Roberts et al, 1993), many workers have suggested an immune-mediated development of resistance. This age-dependent trend, however, could be a result of either behavioral or immunologic changes, because studies in endemic communities have ascertained a general decline in contact with infected water with increasing age (Dalton and Pole, 1978). Nevertheless, recent analyses suggest that even when exposure to infected water is controlled for, age may play a role in the development of resistance.

Eggs that are not promptly expelled from pelvic organs calcify, including those in the bladder and ureters. The accumulation of eggs results in decreased compliance of the urinary tract and increases upper tract pressures. In turn, this promotes the development of urinary stasis, hydronephrosis, and hydroureter (Cheever et al, 1975). The extent of organ calcification can often be identified through radiologic imaging and is roughly correlated with the tissue

burden of calcified eggs (Cheever et al, 1975). The anatomic level of obstruction involves the ureteral meatus (1%), interstitial ureter (10% to 30%), juxtavesical ureter (20% to 60%), lower third of the ureter (15% to 50%), or a contiguous combination of these areas (30% to 60%) (Gelfand, 1948; Smith et al, 1977b; Al-Shukri and Alwan, 1983). Three patterns of hydroureter are associated with urogenital schistosomiasis: segmental (i.e., cylindric or fusiform), tonic, and atonic (Smith et al, 1977a). About one quarter of obstructive uropathy cases involve segmental ureteral dilation, with 80% of those cases occurring in the lower ureter. The dilations occur above areas of concentric ureteral muscular replacement by fibrosis and “sandy patches.” It is unusual for segmental lesions to cause significant hydronephrosis. Up to 30% of obstructive uropathy is caused by tonic hydroureter. This is characterized by dilated, tortuous, thick-walled, and trabeculated ureters with marked ureteral muscular hypertrophy and impaired peristalsis. Typically the entire ureter proximal to an obstructive lesion is involved, generating a functional stenosis. This is often accompanied by significant hydronephrosis, which is reversible if the obstruction is relieved (Smith et al, 1977a). Atonic hydroureters are found in the remaining patients with obstructive uropathy. These ureters are markedly dilated, very tortuous, and thin walled; lack peristalsis; and are associated with atrophic, fibrotic ureteral muscle.

Schistosomal hydroureter typically precedes hydronephrosis (Lehman et al, 1973; Cheever et al, 1978). Left untreated, schistosomal hydronephrosis progresses from worsening renal pelvic dilation to medullary atrophy to medullary effacement and cortical atrophy (Smith et al, 1974, 1977b). This pathophysiologic sequence accounts for the abrogation of tubular function (especially concentrating ability) before compromise of glomerular function (Lehman et al, 1971, 1973).

Patients with chronic *S. haematobium* are at increased risk of bacterial urinary tract superinfections, possibly because the bacteria can affix to the tegument of adult worms, or secondary to urinary stasis or immunomodulation. Patients infected with *S. haematobium* are also at higher risk for bladder cancer, especially squamous cell carcinoma. The relationship between *S. haematobium* and bladder cancer is perhaps the strongest of any helminthic infection–cancer association. This association is supported by both epidemiologic studies (particularly in Egypt) and experimental models (Mostafa et al, 1999). Rates of bladder cancer are linked with duration and severity of infection and are associated with a mortality rate as high as 10.8 per 100,000 males in Egypt (Mustacchi, 2003).

Female genital schistosomiasis (FGS) remains poorly understood. Sequestration of eggs in the female reproductive tract results in the formation of fibrotic nodules, or sandy patches, in the uterus, cervix, and lower genital tract (Badawy, 1962) (Fig. 17-11). Little is known about the mechanism through which *S. haematobium* generates female genital disease aside from the increased vascularization of the female genital mucosa that occurs as a result of the presence of eggs (Jourdan et al, 2011).

Other bladder sequelae of long-term *S. haematobium* infection include the development of urothelial hyperplasia, squamous metaplasia, urothelial dysplasia, and eventually urothelial or squamous cell carcinoma. Bladder cancer is the final pathologic sequela of schistosomiasis. Schistosomal bladder cancer features an early onset (40 to 50 years) and is often squamous cell carcinoma (60% to 90%) or adenocarcinoma (5% to 15%) (Cheever et al, 1978; Lucas, 1982; Al-Shukri et al, 1987; Thomas et al, 1990; Bedwani et al, 1998). Over 40% of schistosomiasis-associated bladder squamous cell carcinomas are well differentiated and verrucous and feature an overall good prognosis. Tumors are found on the posterior wall about half of the time and on the lateral wall approximately 30% of the time. Exophytic neoplasms account for roughly two thirds of schistosomal bladder cancers, and the remainder are ulcerative endophytic tumors. Mass drug administration (MDA) campaigns in Egypt have been associated with an overall reduction of bladder neoplasms from 28% to 12% and a shift from squamous cell carcinomas to transitional cell carcinomas (Gouda et al, 2007). Although transitional cell carcinomas of the bladder are less frequently associated with *S. haematobium* infection (Michaud, 2007),

some epidemiologists believe that the relatively high rate of smoking in schistosomiasis-endemic regions may further increase the risk of bladder cancer, possibly synergistically with *S. haematobium* infection (Bedwani et al, 1998). However, some unselected autopsy series from the same regions have reported similar frequencies of bladder cancers in patients without schistosomiasis (Smith et al, 1977a; Cheever et al, 1978).

Egg deposition into the bladder wall has been implicated as a major factor in carcinogenesis, and *S. haematobium* has been classified as a Class I agent (carcinogenic to humans) by the International Agency for Research on Cancer within WHO (International Agency for Research on Cancer, 2011). Vascular endothelial growth factor (VEGF) is increased in the bladder early after *S. haematobium* egg exposure (Fu et al, 2012; Ray et al, 2012; Salem et al, 2012). VEGF may promote tumor vasculogenesis and facilitate carcinogenesis and/or cancer progression. One potential pathway of schistosomal bladder oncogenesis may be initiated when papillomas merge with the basal transitional epithelium, forming benign fibroepithelial papillary growths. After successive episodes of inflammation and fibrosis, some of the urothelial cells may sequester together (or expand clonally) and form potentially precancerous lesions, including squamous metaplasia (Mustacchi, 2003). Molecular profiling of the mouse bladder indicates that *S. haematobium* egg exposure induces transcriptional alterations in bladder carcinogenesis-related signaling pathways (Ray et al, 2012). Bacterial urinary tract coinfections may also contribute to *S. haematobium*-associated bladder carcinoma, given that *S. haematobium* increases the ability of bacteria to reduce nitrates to nitrosamines, which can alkylate proteins and nucleic acids (Grisham and Yamada, 1992). Resulting mutations in oncogenes (i.e., p53) may then contribute to neoplasia (Mustacchi, 2003).

Clinical Manifestations

Acute schistosomiasis encompasses the transient human responses to cercarial penetration and the longer-lasting responses to schistosome tissue migration and maturation. Chronic schistosomiasis results from the immune response to protracted oviposition, often lasting for years and leading to organ damage. As a result, clinically apparent chronic schistosomiasis is limited to long-term residents of endemic areas, who are continually reinfected, have long-term, high worm burdens, and are re-exposed to eggs. As with most human helminths, *Schistosoma* species cannot complete their life cycle nor replicate in the human host. Thus, in tourists or short-term visitors who are exposed once to the parasite, even in the absence of efficacious chemotherapy, adult worms die of senescence within 3 to 5 years, limiting subsequent pathology.

Acute Schistosomiasis. The first clinical manifestation of schistosomiasis is often an itchy maculopapular rash (cercarial dermatitis), usually within 1 to 2 days of cercarial penetration. The rash usually resolves before travelers have returned from endemic areas, making the diagnosis more difficult (Stuiver, 1984).

Acute schistosomiasis is seen 2 to 8 weeks later in some patients during their primary infection (although it is silent in many). The well-known eponym for acute schistosomiasis, “Katayama fever,” is derived from early descriptions of the syndrome in the Katayama Valley in Japan; it occurs most commonly with heavy primary *S. japonicum* infections, less commonly with *S. mansoni*, and rarely with *S. haematobium*. The initial signs and symptoms of Katayama fever include fever, dry cough, fatigue, headache, diarrhea, eosinophilia, neck pain, and urticaria (Jauréguiberry et al, 2010). Acute schistosomiasis is seen rarely among people living in endemic areas (Meltzer et al, 2006). Because the signs and symptoms of acute schistosomiasis are nonspecific, cases often remain undiagnosed or confused with other endemic diseases such as malaria or enteric fever (Jensen et al, 1995).

Because acute schistosomiasis may be clinically silent, all individuals with exposure to potentially infested water should be aware of the possibility of infection, with considerations for accurate diagnosis and treatment based on these factors (Jauréguiberry et al, 2010).

Chronic Schistosomiasis. Adult *S. haematobium* worm pairs shed eggs into the bladder wall, beginning about 8 to 12 weeks after infection. This is sometimes heralded by painless, recurrent hematuria, dysuria, or urinary frequency (Mahmoud, 2001). In some highly endemic cultures, hematuria in males is seen as a sign of puberty and can be sufficiently severe as to result in anemia (Wilkins et al, 1985). Proteinuria is also often associated with urogenital schistosomiasis. Hematuria is a consistent and specific enough sign of infection that it is used as a primary diagnostic technique in endemic areas. However, given the many other possible causes of hematuria, urogenital schistosomiasis is often unsuspected and misdiagnosed in infected travelers returning to their nonendemic home countries (Raglio et al, 1995).

Long-term urogenital schistosomiasis results in fibrosis that may obstruct urinary drainage and result in organ dysfunction. Egg deposition in the ureters and subsequent granuloma, polyp, and ulcer formation increases the risk of hydronephrosis and hydroureter caused by impaired peristalsis of the walls of the renal pelvis and ureter, which in turn can result in obstruction, and vesicoureteral reflux. Recovery of renal function may be achieved through anthelmintic therapy in shorter-term infections, whereas surgical repair of the ureter or urinary diversion may be necessary during late-stage or more severe disease (Mahmoud, 2001).

FGS is another form of chronic schistosomiasis and occurs in 33% to 75% of females with *S. haematobium* infection as a result of egg deposition into the fallopian tubes, cervix, vagina, vulva, ovaries, and/or uterus (Kjetland et al, 2012). Friable mucosal lesions (sandy patches) can result, which often bleed on contact during pelvic examinations or sexual intercourse (Hotez and Fenwick, 2009). Dyspareunia, pelvic and abdominal pain, vaginal bleeding and discharge, urinary frequency, and infertility are common but resemble signs and symptoms of urinary tract infections (UTIs) and sexually transmitted diseases of other causes, so FGS is often misdiagnosed and left untreated (Hotez and Fenwick, 2009).

Men can carry high numbers of *S. haematobium* eggs in the ejaculatory ducts and seminal vesicles, and blood and/or schistosome eggs may be present in the ejaculate before they are detectable in the urine. Patients with involvement of these urogenital structures often have a testicular mass or scrotal pain. Egg burdens of the epididymis, ovaries, and fallopian tubes are generally higher than those of the testes, uterus, and vagina (Cheever et al, 1977, 1978; Helling-Giese et al, 1996a).

As infection progresses, a late, chronic, active stage develops when tissue egg burdens peak. Chronic suprapubic and pelvic pain with associated urinary urgency, frequency, and incontinence are classic for the schistosomal contracted bladder (Duvie, 1986). Frequently the trigone appears normal or somewhat hyperemic and edematous, whereas the remainder of the detrusor muscle is thickened and indurated, as is the entire bladder wall. Functional bladder capacity can be as low as 50 mL in adults.

Over years, active infection becomes more quiescent, and oviposition and egg excretion occur at a lower rate and symptoms are dampened. Over 30% of light infections become asymptomatic in some endemic regions (Rutasitara and Chimbe, 1985). In spite of this, clinically silent obstructive uropathy may evolve throughout this period as fibrosis replaces polypoid lesions and the bladder and ureters undergo sometimes irreversible damage. As a result, severe hydroureteronephrosis can develop insidiously.

Infected individuals can enter a chronic inactive phase, in which viable eggs are no longer detected in urine or tissues. Signs and symptoms at this stage are caused by sequelae and complications of the immune reaction to the calcified, dead eggs rather than the schistosomal infection itself. Unfortunately, among patients with schistosomal obstructive uropathy, 40% to 60% present to urologists at this end stage (Smith and Christie, 1986). In heavily endemic regions, poorly or nonfunctioning kidneys are common in patients who are asymptomatic. About half of patients will develop bacterial urinary tract coinfections superimposed on their schistosomal obstructive uropathy. The bacteria associated with urogenital schistosomiasis are the same organisms that cause UTIs in patients without schistosomiasis. There is evidence that these coinfections

may occur more readily because of parasite immunomodulation of the host (Hsieh et al, 2014). Some series have noted an association of chronic or recurring UTIs caused by *Salmonella*, often associated with intermittent bacteremia in some patients with urogenital schistosomiasis (King, 2001). This association suggests that *Salmonella* bacteriuria in this setting may actually be “spillover” of bacteremia into the urinary stream. *Salmonella* organisms reside in the apical invaginations of the schistosome tegument, where they are sheltered from host defenses and antibiotics. Awareness of this association can lead to treatment of both infections with good response. Antibiotics alone do not fully resolve this process.

Another manifestation of urogenital schistosomiasis is the development of bladder urothelial ulcers (Smith et al, 1977a). On presentation, acute schistosomal ulcers rarely are in the active stage, when necrotic polyps slough into the urine and leave behind a urothelial ulcer. The more common chronic bladder ulcer is a late sequela of heavy infection. This lesion is associated with a constant burning sensation and intense suprapubic and pelvic pain. The majority of these patients exhibit gross hematuria and pyuria.

Eosinophilia is very common during acute schistosomiasis and is seen even during chronic infection. During chronic infection the eosinophilia is usually low grade, and although neither sensitive nor specific for schistosomiasis, its presence can be a clue that a parasitic infection such as schistosomiasis may be present. Exceptions to this usual sequence of acute and chronic infection may occur and sometimes manifest in the form of ectopic pulmonary schistosomiasis, neuroschistosomiasis, and FGS.

Diagnosis

Finding *S. haematobium* eggs in urine or stool remains the gold standard for diagnosis of active infection, although eggs do not appear until oviposition begins 8 to 12 weeks after initial infection. Because maximal egg shedding in the urine peaks at noon, urine samples should be ideally collected between 9 AM and 3 PM for examination (Doehring et al, 1983, 1985). Urine samples can be concentrated to increase sensitivity and detect low-intensity infections. If eggs are not found in the urine or stool but clinical suspicion remains high and serology is consistent with exposure, tissue biopsy can be considered. A rectal snip biopsy should be performed before a bladder biopsy, because eggs are common in the rectal mucosa and the risk of a bladder biopsy–related complication (e.g., infection, perforation) is avoided. A squash preparation of the biopsy specimen between glass slides is superior to histopathologic analysis, because it is more sensitive and allows determination of egg viability. In potential cases of FGS, microscopic inspection of biopsy samples from lesions on the vulva, vagina, or cervix may result in egg identification and diagnosis (Helling-Giese et al, 1996b). Visual and dipstick-based detection of gross or microscopic hematuria and urine turbidity are also used to indirectly diagnose urogenital schistosomiasis, although these methods are less sensitive and specific and best combined with already-established diagnostic tools; they are most commonly used in the developing world as part of control and elimination campaigns (Adesola et al, 2012).

Serologic tests that combine a Falcon assay screening test–enzyme-linked immunosorbent assay (FAST-ELISA) with a Western blot analysis are available at the CDC (Wilson et al, 1995; Al-Sherbiny et al, 1999). Together, the assays are over 90% sensitive and specific for *S. haematobium* infection. When the diagnosis is suspected but eggs are not present, serology can be useful, but it does not distinguish between acute and chronic infection because antibody titers remain positive even after curative chemotherapy. Other serologic assays are also available at commercial laboratories. Patients generally first become antibody positive about 4 to 6 weeks after infection (Schwartz et al, 2005).

Ultrasonography can also be useful and may demonstrate bladder or ureteral wall thickening, polypoid lesions, hydroureter, hydronephrosis, urinary tract calcifications, and even bladder carcinoma (Kardorff and Döhring, 2001). Plain abdominal radiographs may reveal urinary tract calcifications; a calcified bladder, which may resemble a fetal head in the pelvis, is characteristic of chronic

urogenital schistosomiasis (Fig. 17-12). The prostate, seminal vesicles, posterior urethra, distal ureters, and, occasionally, colon may also demonstrate calcifications.

The earliest radiographic changes on IVU appear to be striations in the ureters and renal pelvis (Hugosson, 1987). Ureteral calcification is typically intramural, and the ureters are dilated. This differs from the calcifications seen in TB, which form casts of nondilated

ureters. Other findings on IVU include hydronephrosis, hydroureter, nonfunctioning kidney, ureteral stenosis, and bladder and ureteral filling defects caused by polypoid lesions. Similar lesions can also be identified through US. With IVU, delayed films are often necessary in the presence of severe obstructive uropathy to discern distended ureters and kidneys. Postvoid views may reveal bladder neck obstruction with retention. Combining IVU with fluoroscopy can differentiate between tonic and atonic ureters (Abdel-Halim et al, 1985) and identify nonstenotic, immobile ureters.

CT can detect both obstructive uropathy and calcified lesions in the colon and urinary tract (Jorulf and Linstedt, 1985), a potential advantage over IVU. MRI does not yet seem to provide enough diagnostic superiority to warrant widespread use (Kohno et al, 2008). Fluoroscopic voiding cystourethrography can detect vesico-ureteral reflux, which occurs in 25% of infected ureters. Cystourethroscopy may reveal mucosal lesions in the bladder (Fig. 17-13). Retrograde fluoroscopic pyelography during cystourethroscopy may reveal important details regarding ureteral anatomy and drainage.

Antigen detection or PCR may be a more sensitive means of diagnosis. Serum or urine samples from infected individuals can be tested for the presence of circulating anodic antigens (CAAs) and circulating cathodic schistosome antigens (CCAs). CAAs and CCAs are specific for active infection because they are released only by viable adult worms and have the added benefit of producing quantitative measurements useful for determining infection severity (Kremsner et al, 1994; Agnew et al, 1995). Moreover, the development of an ELISA reagent strip test for urine samples has allowed for point-of-care detection of CCAs that is more user-friendly and field applicable (van Dam et al, 2004). However, in some hands the CCA test completely failed to detect *S. haematobium* infection (versus more than 80% sensitivity and specificity for detection of *S. mansoni* infection) (Stothard et al, 2006), and it is relatively expensive for wide-scale use in the developing world.

By far the most sensitive method for diagnosing urogenital schistosomiasis from urine or even stool samples is PCR (Obeng et al, 2008; ten Hove et al, 2008). PCR is also highly sensitive and specific for diagnosing FGS from vaginal lavage samples, although detection may vary based on patient age and length of infection (Kjetland et al, 2009). Unfortunately, PCR is difficult to use in the developing world and in the field because it requires highly trained technicians and the use of organic solvents and commercial kits. Still, in the context of transmission control and disease surveillance, especially in settings of low-intensity transmission, PCR is a useful option.

Globally, many cases of urogenital schistosomiasis remain undetected and untreated because most are diagnosed only through direct egg detection rather than more sensitive methods. The need for more reliable and accessible diagnostic tools is thus particularly important for the development of more effective schistosomiasis control strategies in the developing world.

Figure 17-12. Bladder calcification in a 30-year-old Egyptian farmer. **A**, Plain x-ray film of the abdomen shows a rim of calcification surrounding the urinary bladder (arrows). **B**, Abdominal ultrasound study shows a bright line surrounding the bladder with a definite dark rim behind it (arrows). (A and B, Courtesy G. Thomas Strickland, MD. From Abdel-Wahab MF, Ramzy I, Esmat G, et al. Ultrasonography for detecting *Schistosoma haematobium* urinary tract complications: comparison with radiographic procedures. *J Urol* 1992;148:346.)

Figure 17-11. Macroscopic appearance of human urinary schistosomiasis. **A**, Urinary bladder opened with an anterior Y incision. The posterior and apical walls have many erythematous, granular, sessile, and pedunculated polyps (arrow), characteristic of the early active stage of urinary schistosomiasis. **B**, Coronal section through the apex of a formalin-fixed urinary bladder. The lamina propria has been expanded and is replaced by a yellow-tan, finely granular, sandy patch (arrow), which is characteristic of chronic inactive foci. Small sandy patches are sprinkled through the fibrotic, atrophic detrusor muscle, even in perivesical fat. The more superficial erythematous portion of the lamina propria contains some viable eggs with granulomatous response (chronic active stage of urinary schistosomiasis). **C**, Coronal section through the middle of a urinary bladder after formalin inflation and fixation. The lamina propria (arrow) has been replaced by a concentric sandy patch, most prominent at the margin of the exophytic, moderately differentiated squamous cell carcinoma. The bladder wall is attenuated except for the tumor (t). No evidence of recent oviposition was found in the lower urinary tract (chronic inactive stage of urinary schistosomiasis, usually found with the bilharzial bladder cancer syndrome). **D**, Urinary bladder opened with anterior Y incision shows several features of severe chronic inactive urinary schistosomiasis. The entire lamina propria has been replaced by a sandy patch. Foci of epidermization are seen at or near the white arrow. The left ureteral orifice (right) is markedly dilated (the so-called golf-hole ureter of schistosomal uropathy). The right ureteral orifice (point of black arrow) is markedly stenotic. **E**, Rectosigmoid colon with polyposis. Numerous sessile and pedunculated polyps are visible. Many are erythematous, indicative of active oviposition with granuloma formation. Some have necrotic hemorrhagic tips. **F**, Mucosal surface of partial cystectomy specimen (4- to 5-cm ellipse) from a patient with the chronic inactive stage of the disease. There is a stellate chronic schistosomal ulcer. Despite the inactivity of the disease, these ulcers may bleed profusely. Pale mucoid flecks at the margin of the ulcer (arrow) are areas of adenoid (goblet cell) metaplasia.

Figure 17-13. A to C, Cystourethroscopic views of bladder lesions. Both papillary mucosal and submucosal lesions are seen in the bladder of a child from Somalia who underwent cystourethroscopy for evaluation of intermittent hematuria and dysuria. (Courtesy Craig Peters, MD.)

Treatment

Medical Management. Praziquantel (PZQ) is currently the only WHO-recommended drug for schistosomiasis (WHO, 2014a) and has replaced metrifonate and oxamniquine as the main therapeutic agent. Although dependence on a single drug increases the potential for parasitic resistance, PZQ's efficacy, widespread availability, and low toxicity are favorable factors, and there has been little incentive for the development of alternative drugs. Two 20-mg/kg oral doses of PZQ are given on the same day, 6 to 8 hours apart (or alternatively, one 40- or 60-mg/kg dose) for *S. haematobium* infections. Corticosteroids are often added for the treatment of acute schistosomiasis (Katayama fever).

As measured by egg reduction and cure rate, PZQ's efficacy is 60% to 90% (Danso-Appiah et al, 2008; Doenhoff et al, 2008). Even in those not cured, the worm burden is likely substantially reduced, which significantly decreases the chances of development of further infectious sequelae. After treatment of a patient with PZQ, it is reasonable to monitor egg counts in urine and stool specimens and to perform serial ultrasonographic studies of the urogenital tract to assess response to drug therapy. Repeat PZQ courses can be given if there is a concern for persistent infection.

PZQ has a favorable pharmacokinetic and side effect profile. The most common side effects (abdominal pain, nausea, headache, and dizziness) are typically mild, generally occur within 3 to 4 hours after administration, and resolve spontaneously. Most patients experience few or no side effects (N'Goran et al, 2003). However, PZQ pills are large and bitter tasting, making oral administration difficult to tolerate, especially for children (Meyer et al, 2009). Perhaps because of its FDA classification as a Pregnancy Category B

drug (deemed safe in lactating and pregnant women based only on animal studies), many chemotherapy programs exclude pregnant and lactating women. However, there are few reports of adverse effects of PZQ among the millions of pregnant women treated with PZQ (Olds, 2003).

PZQ is less efficacious against schistosomulae than adult worms, which might partly explain the lower cure rates in areas with high rates of schistosomiasis transmission and reinfection. In addition, it means that PZQ cannot be used to abort infection shortly after exposure. Multiple PZQ doses administered several weeks apart can ensure that juvenile schistosomes missed by the first administration are eradicated after maturation (Doenhoff et al, 2008).

Whether schistosomes are developing resistance to PZQ is debatable. Most large studies conducted on *S. haematobium*-infected individuals suggest little drug resistance in endemic areas (King et al, 2000; Guidi et al, 2010). However, there have been reports of PZQ failures in the treatment of travelers or military personnel returning from endemic areas (Doenhoff et al, 2008). Even if resistance to PZQ is not already evolving, it could occur in the future. It is hoped that use of alternative drugs and combination of drug treatment programs with environmental control programs (snail control and sanitation improvement) may lower transmission and reduce the use of PZQ enough to prevent this.

Artemisinin and its analogues (artemether and artesunate, currently in use as antimalarials) are chemoprophylactic alternatives to PZQ because they specifically target the schistosomular stage of *S. haematobium*. Artemether and artesunate are 90% to 97% efficacious in preventing schistosomiasis but are poor treatments for established infections. Combined administration of PZQ and

artemisinin derivatives results in lower infection rates than PZQ alone and thus offers a valuable tool for MDA programs, especially in areas of high transmission and reinfection rates. However, a major concern regarding the use of artemisinins in this manner is the induction of malaria resistance to artemisinin derivatives. Because of this, widespread PZQ–artemisinin derivative combination therapy should not be used in schistosomiasis-malaria co-endemic areas (Liu et al, 2011).

Surgical Management. The efficacy and ease of PZQ therapy for urogenital schistosomiasis, together with the possible reversibility of early-stage disease (Richter et al, 1996; Richter, 2000), mean that in most patients trials of medical therapy should be undertaken before elective surgical approaches (Cioli et al, 1995). In general, surgery is reserved for complications that have not responded to adequate medical treatment within a reasonable follow-up period and for those settings in which immediate surgical intervention is necessary. For example, severe bladder hemorrhage is one common cause for urgent surgical intervention.

Prostatitis and prostatic enlargement are uncommon in schistosomiasis. Accordingly, numerous autopsy studies have failed to demonstrate evidence of anatomic bladder outlet obstruction (Smith et al, 1974; Cheever et al, 1977, 1978). However, clinical studies consistently report cystoscopic (Fam, 1964), urodynamic (Sabha and Nilsson, 1988), and elevated postvoid residual urine volumes, which are evidence of functional bladder outlet obstruction that occasionally requires surgical intervention in patients with severe inactive urinary schistosomiasis (Abdel-Halim et al, 1985). *S. haematobium* infection–associated scrotal induration, pain, and enlargement associated with epididymitis can lead to surgery being performed for the suspicion of a testicular tumor.

Surgery is indicated for irreversibly contracted bladders; procedures include vesical denervation, urinary diversion, ileocystoplasty, and hydrodistention. Any treatment, however, must be performed in conjunction with medical chemotherapy. Chronic, deep bladder ulcers may necessitate a partial cystectomy, because fulguration rarely produces either symptomatic relief or ulcer healing. Urothelial hyperplasia is strongly associated with severe urogenital schistosomiasis, whereas urothelial dysplasia and metaplasia commonly accompany schistosomal bladder cancer (Khafagy et al, 1972). Treatment of bladder cancer secondary to schistosomiasis is typically surgical and discussed elsewhere (see Chapters 92 to 96).

The most frequent sequelae of urinary schistosomiasis result from ureteral involvement causing obstructive uropathy (Lehman et al, 1973; Smith et al, 1974; Cheever et al, 1978; Smith and Christie, 1986). Hydroureter and hydronephrosis are linked to the intensity of *S. haematobium* infection. Because ureteral obstruction observed during schistosomiasis is most often caused by concentric or hemiconcentric polypoid lesions that “girdle” the ureteral muscle in the intramural and adjacent extravascular ureter, it often responds well to medical management alone. Complete resolution of deteriorated renal function caused by active infection–associated obstructive uropathy responds within 1 to 2 months of PZQ chemotherapy (Lehman et al, 1973). Chemotherapy not only reverses schistosomal obstructive uropathy but can also prevent it, even in persons who are continually reinfected (Subramanian et al, 1999). However, in late, chronic, active and inactive urinary schistosomiasis, anatomic obstruction may be less amenable to chemotherapeutic cure.

Anatomic ureteral stenosis, with or without calculi, has been identified in up to 80% of patients with ureteral obstruction (Lehman et al, 1973; Smith et al, 1977b; Al-Shukri and Alwan, 1983; El-Nahas et al, 2003). When residual ureteral stenosis persists after chemotherapy, it is usually amenable to surgical intervention. Depending on the location and extent of the stricture, procedures involving dilatation or excision have been employed. Balloon dilatation is efficacious with anatomic stenosis (Jacobsson et al, 1987), but mechanical dilatation is frequently plagued by recurrent stenosis (Wishahi, 1987). When the ureteral meatus, intramural ureter, ureterovesical junction, or distal ureter is involved, options to reconstruct a functional valve include a variety of plastic operations. Most of these procedures

are variants of the Politano-Leadbetter operation (Politano and Leadbetter, 1958; Leadbetter and Leadbetter, 1961). Although the procedures are highly efficacious for some patients (Smith et al, 1977b; Al-Shukri and Alwan, 1983), other authors have noted that restenosis can occur (Umerah, 1981).

In long or multifocal lesions of the ureter, excision of the affected portion may leave an inadequate residual ureter for reimplantation or simple ureteroureterostomy; in these patients, surgeons have successfully employed the Boari flap, ileal conduit, suprapubic intravesical ureterostomy (in which the obstructed ureteral segment is bypassed with use of a peritoneal dialysis catheter and drained into the bladder), and replacement of the ureter with ileal segments, taking care to maintain an isoperistaltic direction of the ileal segment (Abdel-Halim, 1980, 1984; Al-Shukri and Alwan, 1983; Abu-Aisha et al, 1985). Isolated meatal stenosis of the ureter may be amenable to simple meatoplasty (Al-Shukri and Alwan, 1983). When a ureter is hopelessly obstructed and cannot be reconstructed, long-term nephrostomy drainage is another option.

Prognosis

Approximately 112 million people are infected with *S. haematobium*, but most have mild infections and a good prognosis. The morbidity and mortality of urogenital schistosomiasis is determined by the overall intensity of infection and genetic polymorphisms for relevant immune response genes (Kouriba et al, 2005; He et al, 2008; Isnard and Chevillard, 2008; Isnard et al, 2011; Ouf et al, 2012). In regions of low *S. haematobium* prevalence, such as Nigeria, essentially no schistosomiasis-related mortality is observed and the frequency and severity of schistosomal obstructive uropathy are low. In contrast, when Egypt had a prevalence of 50%, schistosomiasis contributed to mortality in 10% of *S. haematobium*–infected individuals (Smith et al, 1974; Cheever et al, 1978). Among patients with severe disease, mortality approached 50% in 2 to 5 years (Lehman et al, 1970).

Patients who die of schistosomal obstructive uropathy (bilateral end-stage hydronephrosis or unilateral hydronephrosis with contralateral nonschistosomal end-stage renal disease) are typically in their 20s and have heavy total egg burdens. Patients who develop the complications of pyelonephritis and urothelial cancer are commonly older than age 40, consistent with time- and intensity-related pathology (Christie et al, 1986; Smith and Christie, 1986).

The prognosis for patients with urinary tract lesions has dramatically improved with PZQ therapy. In children with obstructive polyps, the uropathy usually completely resolves within 2 to 6 weeks of treatment. For patients with chronic obstructive uropathy from sandy patches and fibrosis, the prognosis is less clear. Some individuals tolerate advanced obstructive uropathy with little, if any, deterioration in renal function. Schistosomal obstructive uropathy, urolithiasis, bladder outlet obstruction, and bacterial cystitis all predispose to pyelonephritis. Bacterial superinfection can be life-threatening and should be treated aggressively and promptly. Finally, for those who develop a bladder malignancy, their prognosis is dependent on the aggressiveness of their tumor.

Prevention and Control

Travelers to endemic areas should be advised to avoid contact with potentially infested fresh water (streams, rivers, ponds, and lakes). Fast-flowing water can still harbor *S. haematobium*. Heating water to more than 125° F for 5 minutes kills the cercariae, as does chlorination and allowing the water to stand for more than 2 days in a setting free of snails. Since the advent of PZQ in the late 1970s and its subsequent mass distribution beginning in the 1980s, schistosomiasis has become relatively simple and affordable to treat, but it remains difficult to control. For the past three decades, control efforts have focused heavily on reducing morbidity using periodic, typically annual targeted mass drug treatments with PZQ, a strategy advocated by WHO. However, when access to safe water is not available, rural poor communities are

subject to vicious cycles of infection, treatment, and reinfection, making more frequent PZQ administration necessary. Sanitation improvements, health education, and snail control are approaches used to break the cycle of transmission, by slowing or halting the influx of eggs into the aquatic habitat, decreasing individual exposure, and reducing the availability of snail intermediate hosts, respectively. Although PZQ is inexpensive, the cost-effectiveness of chemotherapy fluctuates widely among MDA settings as a result of variations in the number of doses of PZQ given per person, variability in transportation and delivery costs, and the potential to take advantage of preexisting public health control programs or other infrastructure (Brooker et al, 2008). The per-person cost in control campaigns is typically under U.S. \$0.50—although even this modest cost, at sufficient scale, may exceed the available resources of many endemic countries (Hotez et al, 2009). Fortunately, a number of pharmaceutical companies and foundations are donating PZQ for use in MDA campaigns.

Because asexual reproduction in the snail host allows the parasite to amplify rapidly, sanitation programs and drug treatment campaigns must reduce egg input into the environment by nearly 90% before a substantial decrease in transmission can be achieved (Woolhouse, 1992). Reductions in snail populations, in contrast, can theoretically effect proportional decreases in disease transmission risk (Woolhouse, 1992). However, considering that adult worms can live for years in the human host, without concurrent mass treatment snail population control alone would need to persist for many years to eliminate transmission. Thus, integrated campaigns focusing on three aims (treating human patients, reducing contact of humans and their wastes with infested water, and controlling snails) offer the most promise.

Other control efforts include mollusciciding (Zhang and Jiang, 2011; Knopp et al, 2012, 2013), biologic control using snail predators or competitors (Roberts and Kuris, 1990; Mkoji et al, 1999; Pointier and Jourdan, 2000; Allen and Victory, 2003; Coelho et al, 2004; Sokolow et al, 2014), and vaccine development (although an efficacious vaccine currently remains out of reach) (Bethony et al, 2008; Gray et al, 2010). Water, sanitation, and hygiene (“WASH”) programs are also, once again, taking center stage and feature many additional benefits beyond potential schistosomiasis reduction (Soares Magalhães et al, 2011; Giné Garriga and Pérez Foguet, 2013).

Schistosomiasis has been eliminated in 10 countries to date (Iran, Japan, Lebanon, Malaysia, Martinique, Montserrat, Morocco, Thailand, Tunisia, and Turkey) (Amarir et al, 2011; Rollinson et al, 2013). At the 65th WHO World Health Assembly (May 2012), resolution WHA65.21 was passed, calling on the global community to “make available the necessary and sufficient means and resources ... to intensify control programmes in most disease-endemic countries and initiate elimination campaigns, where appropriate” (WHO, 2012). Representing a shift from morbidity control to a new focus on elimination, this marks an exciting and hopeful milestone in the global fight against schistosomiasis.

KEY POINTS: SCHISTOSOMIASIS

- *S. haematobium* worms can survive in human hosts for years to decades. A careful travel and social history is crucial to identify potential exposures, correlate them with urogenital symptoms, and determine the need to perform specific diagnostic assays.
- Praziquantel therapy of early stage urogenital schistosomiasis can reverse inflammatory lesions, including fibrosis, of the urinary tract caused by the host response to eggs deposited in tissues.
- The gold standard for diagnosis of active urogenital schistosomiasis is the identification of eggs in urine, stool, or bladder or rectal biopsy specimens. Serologic and PCR-based assays are highly sensitive but may not distinguish between active and resolved infection, and are impractical in endemic regions.

Filariasis

The filariae are vector-borne tissue nematodes. Human pathogens in this group include the agents of **lymphatic filariasis** (LF), *Onchocerca volvulus*, and *Loa loa*.

LF is caused by the mosquito-borne helminths *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*. The symptoms of LF range from acute lymphatic inflammation to chronic lymphatic dilation with hydrocele, lymphedema, and elephantiasis of the limbs.

Organisms

W. bancrofti, *B. malayi*, and *B. timori* are threadlike nematodes. Infective (third-stage) larvae are transmitted to humans by mosquito bites. After entering humans, larvae migrate to central lymphatic vessels and eventually mature (over 6 to 9 months) into adult male or female worms. Adults (approximately 20 to 100 mm × 0.2 mm) are considerably larger than microfilariae (approximately 200 μm × 10 μm) (Fig. 17-14). Adult worms live primarily in the afferent lymphatics, especially in the lower extremities (inguinal, iliac, and periaortic lymphatics), and (for *W. bancrofti* only) male genitalia (epididymis, spermatic cord, testicles). Adult worms live approximately 5 to 7 years.

After mating with males, female worms release large numbers of microfilariae. In most endemic areas, *W. bancrofti* and *Brugia* microfilariaemia peaks in the middle of the night as an adaptation to facilitate transmission, coinciding with peak local mosquito vector activity. In some parts of the Pacific, the periodicity of *W. bancrofti* is diurnal rather than nocturnal. After mosquito ingestion, microfilariae mature over 10 to 14 days into infective third-stage larvae.

W. bancrofti and *Brugia* species harbor an obligate rickettsia-like endosymbiont (*Wolbachia*). These endosymbionts are involved in embryogenesis, and antimicrobial therapy (e.g., doxycycline) kills them, resulting in decreased microfilariae release and suppressed larval molting (Hoerauf et al, 2001).

Epidemiology

Globally, 120 million people are infected with LF. Over 90% of infections are caused by *W. bancrofti*, mostly in sub-Saharan Africa, South and Southeast Asia, and the western Pacific. In the Americas, *W. bancrofti* is endemic only to Haiti, the Dominican Republic, Guyana, and Brazil. Infection with *B. malayi* is limited to Asia and several Pacific islands (e.g., Indonesia and the Philippines). *B. timori* infection occurs only in southeastern Indonesia. Within a given

Figure 17-14. Microfilaria of *Wuchereria bancrofti* in peripheral blood. (Courtesy Division of Parasitic Diseases and Malaria, Centers for Disease Control and Prevention.)

geographic area, the distribution of LF is often quite heterogeneous. Several genera of mosquitoes are capable of transmission, including *Anopheles* (rural Africa and the Pacific), *Culex* (urban areas, especially India), *Aedes aegypti* in some Pacific islands, and others.

Although varying among different locales and mosquito vectors, transmission of LF is relatively inefficient, and obstructive lymphatic disease is generally seen only in persons repeatedly infected over many years (i.e., usually long-term residents of endemic areas). In endemic communities, prevalence increases from childhood through the third or fourth decade of life, after which it remains fairly constant (because of the gradual accumulation of adult-stage worms in the population over time). Lymphedema and genital disease are rare before age 10 but increase in prevalence with age. Overall, about one third of infected persons have clinically overt disease. The likelihood of developing clinical manifestations is particularly high in India, Papua New Guinea, and Africa, whereas it is lower in the Americas (Kazura et al, 1997).

Pathology and Clinical Manifestations

The initial immune response to infective larvae and early adult worms is mostly proinflammatory (involving both Th1 and Th2 T-cell responses). The contribution of humoral immunity includes an increase in filaria-specific IgE titers. Eosinophil-mediated killing of microfilariae also likely plays a role. With the onset of microfilaremia, T-cell responses decrease, mediated by IL-10, IgG4-blocking antibodies, and antigen-specific suppressor T cells. Whether protective immunity develops has been difficult to determine, but groups of individuals have remained infection free despite long-term exposure in highly endemic settings (Steel et al, 1996).

Clinical manifestations in infected patients vary greatly, ranging from subclinical infection to severe disfigurement of the limbs and genitalia. Damage from established infection is cumulative because of progressive scarring and lymphatic obstruction. Medical therapy does not readily reverse such damage but can prevent further progression in patients with active LF infection. Although rarely fatal, LF can cause severe disability and among parasitic infections is responsible for the third highest number of disability-adjusted life years (DALYs) lost globally.

The mechanisms leading to lymphedema have been poorly established. However, parasite-derived factors are at least partly responsible for initial lymphatic dilatation, with subsequent contributions from secondary bacterial infections and inflammatory responses to dying or dead parasites. *Wolbachia* endosymbionts also appear to drive a proinflammatory response. Lesions vary from nodular inflammation to suppuration, histologically appearing as granulomas around worms, sometimes with tissue eosinophils (Fig. 17-15). A vicious cycle can result, with acute attacks worsening lymphedema, predisposing to more secondary infections, worsening lymphedema, and so on; episodic filarial inflammation eventually abates, leaving obliterated lymphatics surrounded by scar tissue. Elephantiasis or hydrocele is then the end stage in some patients.

Subclinical Infection. Most LF-infected persons have few overt clinical manifestations, even with high-grade microfilaremia. However, though the infection is clinically asymptomatic, virtually all persons with patent *W. bancrofti* or *B. malayi* infection have at least some subclinical disease (e.g., dilated lymphatics, scrotal lymphangiectasia, microscopic hematuria, or proteinuria). Eosinophilia is also very common with most forms of LF.

Acute Adenolymphangitis. Acute adenolymphangitis (ADL) is often the first clinical manifestation of LF, consisting of fever, lymphadenitis, lymphangitis, and edema that usually lasts days to a week. The lymphangitis is retrograde (extending peripherally), which distinguishes it from bacterial lymphangitis. Although all four extremities can be involved in both bancroftian and brugian filariasis, the genital lymphatics are affected almost exclusively by *W. bancrofti* infection. This can result in funiculitis, epididymitis, scrotal pain, tenderness, and lymph scrotum (ruptured lymphatic vesicles on the scrotal skin that yield a whitish discharge and secondary bacterial infections).

Figure 17-15. Section of an adult *Brugia* organism in a lymph node. (Courtesy Division of Parasitic Diseases and Malaria, Centers for Disease Control and Prevention.)

Another acute manifestation, **dermatolymphangioadenitis** (DLA), is characterized by fever, chills, myalgias, and headache. Edematous inflammatory plaques occur, as well as hyperpigmentation, vesicles, and ulcers, often at the site of an inciting skin injury. Inflammation progresses proximally and is thought to be secondary to bacterial infections.

Lymphedema. Lower or upper extremity edema is the most common chronic manifestation of LF, with lower extremity edema being the more prevalent. Bancroftian filariasis typically involves the entire limb, whereas brugian filariasis usually involves only the leg below the knee. Although both lower extremities are often affected, asymmetrical involvement is most common. The overlying skin may exude serous fluid. Breast involvement can also occur in females.

Genitourinary Manifestations. Male genital involvement is very common with bancroftian filariasis but uncommon with *Brugia* infection. The prevalence of female genital involvement has not been well established, although anecdotal evidence suggests that it is uncommon (Nutman and Kazura, 2011). Genital disease is not usually experienced until at least the teenage years. Acute painful episodes of (usually unilateral) epididymitis or funiculitis accompanied by fever and malaise can last several days and are one of the most common consequences of bancroftian filariasis.

Funiculoepididymitis. Funiculoepididymitis is characterized by palpable cordlike swellings and edema. Although the condition is usually self-limited, recurrences and the subsequent development of chronic lymphedema are common. Filarial funiculitis rarely results in sterility or orchitis, because the spermatic cord usually remains uninvolved. This manifestation is often mistaken for malignancy, and many patients undergo surgery as a result (including orchiectomy). Varicocele may complicate inflammation, increasing pain and swelling. Bacterial superinfection is a rare but severe complication, with exquisite pain and septic thrombophlebitis often present.

Hydroceles. Chronic disease of the male genitals often results in hydroceles, which can be very large (Fig. 17-16). In endemic areas, differentiation of filarial from nonfilarial hydrocele is difficult, and parasites are rarely detected in the hydrocele fluid. Hydrocele accompanied by nodules in the cord or epididymis and a history of travel to or residence in an endemic area suggests LF. A thick,

Figure 17-16. Huge hydrocele and scrotal elephantiasis. (Courtesy Dr. B. H. Kean. From Zaiman H. A pictorial presentation of parasites, Valley City, ND.)

fibrous tunica, especially with cholesterol or calcium deposits, also suggests LF.

Hydroceles are usually painless unless complicated by acute epididymitis or funiculitis. The scrotal skin may also be thickened and brawny as a result of lymphedema, with oozing lymph. Patients with filarial hydrocele rarely experience bacterial superinfection, although those with elephantiasis and lymph scrotum are often superinfected.

Scrotal and Penile Elephantiasis. Mild scrotal edema is not unusual during early infection or with established hydrocele. Conversely, penile edema is unusual, and massive enlargement of the scrotum or penis occurs late, largely in individuals with poor access to medical care. Genital elephantiasis rarely arises from causes other than LF.

Chyluria. Chyluria occurs when GU tract lymphatics are damaged, resulting in lymph passage into the urine and massive fat and protein loss. Although rare, this can result in serious nutritional consequences. It usually occurs earlier in the natural history of filariasis than genital elephantiasis. Chyluria is usually intermittent and may spontaneously remit.

Tropical Pulmonary Eosinophilia. Tropical pulmonary eosinophilia (TPE) is a syndrome characterized by paroxysmal cough and wheezing (usually nocturnal), fever, adenopathy, high-grade eosinophilia, and elevated IgE levels. It is caused by an allergic response to microfilarial antigens and is seen most commonly in South and Southeast Asia. Chest radiographs range from normal to diffuse reticulonodular infiltrates, and pulmonary function tests show restrictive (and sometimes obstructive) defects. If done, lung biopsy reveals an eosinophilic interstitial pneumonitis. Microfilaremia is usually absent.

Diagnosis

In residents of endemic areas, lymphedema or male genital disease is epidemiologically more likely a result of LF than a similar presentation in the developed world (assuming no other cause of secondary edema is present). Still, tuberculosis, *S. haematobium* infection (urogenital schistosomiasis), and gonorrhea may also produce funiculoepididymitis and are in the differential diagnosis. In addition, nonfilarial hydrocele is common in both tropical and

nontropical areas. However, hydrocele occurs at an earlier age and with greater frequency in filariasis-endemic areas.

For parasitologic confirmation, it is difficult to visualize adult worms directly because they are localized in the lymphatics; they are usually seen only via histologic examination of surgical or biopsy specimens (in which visualizing adult worms is diagnostically definitive but insensitive). However, ultrasound examination of lymphatics has at least 80% sensitivity in some settings, in part because live adult worms have a distinctive pattern of movement (the “filaria dance sign”) (Amaral et al, 1994). Online examples can be found at www.youtube.com/watch?v=ER1BFx4_qGc, <http://www.filariajournal.com/content/2/1/3/figure/F1?highres=y>, and www.youtube.com/watch?v=d3KWh6xqQm0. Plain radiographs may reveal calcifications, which are also suggestive of LF in the appropriate clinical setting.

Microfilariae can be found in blood and occasionally in other body fluids; they are best detected by a Giemsa-stained blood smear. The timing of blood collection should be based on the periodicity of the microfilariae in the geographic location involved (highest at midnight in most cases). Microfilaremia is found in only 30% to 40% of all infections, and definitive diagnosis in amicrofilaremic cases can be more difficult. Detection of circulating *W. bancrofti* antigens is one means to detect such infections, and this can be done with both an ELISA and a point-of-care immunochromatographic card test (ICT). Recently, a new ICT (the Alere Filariasis Test Strip) has shown better sensitivity in field conditions than the BinaxNOW Filariasis ICT, which has been in use for the past 10 to 20 years (Weil et al, 2013). There are currently no tests for circulating antigens in brugian filariasis. PCR-based assays for *W. bancrofti* and *B. malayi* in blood are very sensitive but are not yet widely available.

Antibody-based assays for diagnosing LF have traditionally suffered from poor specificity. IgG4 antibodies are less cross-reactive to nonfilarial helminth antigens and thus are more specific. Specificity has also been improved with species-specific antigens for both brugian and bancroftian infection. A dipstick antibody test has been developed for brugian filariasis (Weil et al, 2011).

Patients with so-called burned-out infections (e.g., those who have received antiparasitic therapy or who departed endemic areas years previously and in whom the worms have now died) often have lasting damage (i.e., lymphedema, genital disease, and other clinical manifestations). In these patients, negative testing for microfilaremia and circulating antigens does not exclude the possibility that their lesions could be a result of LF. However, such patients are usually LF antibody positive.

Radionuclide lymphoscintigraphic imaging reliably demonstrates lymphatic abnormalities in patients with LF. Although helpful in documenting the degree of damage associated with infection, this is not useful for differentiating LF from other causes of lymphatic disease.

Treatment

Because most patients with microfilaremia have at least subclinical disease, treatment is recommended for both symptomatic and asymptomatic individuals with microfilaremia. Diethylcarbamazine (DEC, 2 mg/kg orally three times a day) is the treatment of choice for active LF (microfilaremia, antigen positivity, or live adult worms on ultrasound). A 1-day course appears to be as effective as the traditional 12-day regimen for most patients (CDC, 2013a), although those with TPE should receive a 2- to 3-week course. DEC kills microfilariae but has only modest activity against adult worms, and in the United States is available only through the CDC (phone: 404-718-4745). DEC should not be given to persons from areas co-endemic for onchocerciasis or *L. loa* (e.g., West and Central Africa) unless these infections have been excluded because of potentially serious side effects related to the killing of these parasites by DEC. Alternatives for LF include albendazole and ivermectin. Albendazole (400 mg orally twice daily for 21 days) has both microfilaricidal and macrofilaricidal activity, but the activity of ivermectin (150 to 400 µg/kg orally once) is limited mostly to microfilariae.

Side effects of DEC include fever, chills, arthralgias, headaches, nausea, and vomiting. In heavily infected patients, painful skin nodules, lymphadenitis, and epididymitis may occur as a reaction to dying parasites or *Wolbachia* endosymbionts, usually days to weeks after initiation of therapy. Ivermectin has a side effect profile similar to DEC when used for LF; it also must be used with caution if co-infection with *L. loa* is possible. Albendazole (when used in single-dose regimens; see later) has relatively few side effects when used for LF.

Doxycycline (200 mg daily) augments the suppression of microfilaremia induced by antifilarial drugs and has some macrofilaricidal activity. Prolonged courses (4 to 8 weeks) render adult worms sterile (Kappagoda et al, 2011). Individuals treated with doxycycline can experience substantial improvements in lymphedema and hydrocele. These benefits are seen even in lymphedema patients without active infection, suggesting that the benefit of doxycycline extends beyond the macrofilaricidal and anti-*Wolbachia* activity of this drug (Mand et al, 2012). The prolonged course is problematic for administration in the developing world, and doxycycline cannot be given to pregnant women or young children. However, in the United States a 6-week treatment course of this drug is a reasonable consideration in properly selected patients.

In persons with chronic lymphedema, prevention of secondary bacterial infections, good hygiene, elastic stockings, elevation, and physiotherapy are important for morbidity control. Antiparasitic therapy in these patients should be reserved for those with active infection. Surgical correction is challenging and often unnecessary. Lymphatic-venous and nodal-venous anastomoses for elephantiasis have been somewhat successful in decreasing leg swelling, as has reconstructive surgery for genital involvement. The long-term effects of these intensive surgical techniques have not been determined.

Genital elephantiasis is rarely amenable to surgery, and lymphadenectomy may further compromise lymph drainage and worsen symptoms. In some cases of funiculoepididymitis, surgery, such as decompression or excision of filarial nodules, might be indicated to preserve the testis and spermatic cord. When funiculoepididymitis is recurrent, painful, and deforming or complicated by blood vessel involvement, more radical surgery is warranted. Drainage of hydroceles provides immediate relief, although recurrence is common in the absence of medical and definitive surgical therapy. Hydrocelectomy is often indicated for large or symptomatic hydroceles. Excision of the intact hydrocele sac is the procedure of choice; alternatively, inversion with partial excision can be considered. When identified, leaking or dilated lymphatic vessels should be sutured or excised. Small hydroceles that do not enlarge usually do not require surgery. Reconstruction of the scrotum or vulva, with removal of redundant tissue, can also provide symptomatic relief to selected patients.

Prevention and Control

Individual protection against LF infection involves avoidance of infected mosquitoes through personal protective measures and long-lasting insecticide-treated bednets (LLINs); LLINs have recently been shown to be a valuable tool for the control and elimination of LF (Reimer et al, 2013). Elimination of microfilariae within communities can interrupt transmission because patent microfilaremia is necessary for mosquitoes to transmit the infection from person to person. However, because chemotherapy does not kill all of the adult worms, it is necessary to continue intermittent administration of antiparasitic drugs for many years, until the adult worms die of senescence. This strategy can be effective for *W. bancrofti* elimination (Molyneux, 2009) but is more challenging in *Brugia*-endemic areas because animals also serve as reservoirs of infection for the latter. MDA campaigns (involving distribution of single annual doses of albendazole plus either DEC or ivermectin, which have a sustained microfilaricidal effect, to most of the population) are the mainstay of control programs in Africa (albendazole/ivermectin) and elsewhere (albendazole/DEC). These campaigns have been successful in control and elimination of LF, especially in

many of the endemic middle-income countries of Asia, Latin America, and the Pacific.

Onchocerciasis, also known as **river blindness**, is a filarial infection caused by *O. volvulus*. The infection is transmitted by *Simulium* black flies; 99% of onchocerciasis cases are found in Africa, with limited foci in Latin America and the Arabian Peninsula. About 37 million people are infected globally (Taylor et al, 2010). As with LF, transmission is inefficient and highly focal. Adult worms live in subcutaneous nodules (mean life span, 9 to 10 years) and release microfilariae that travel through the skin (and eye). *O. volvulus* adults also harbor *Wolbachia* endosymbionts. Infection classically causes dermatitis, keratitis, and chorioretinitis, with blindness as an end result after many years, from corneal scarring. Diagnosis is confirmed by microscopically examining skin snips for microfilariae, finding adult worms in subcutaneous nodules, or seeing microfilariae in the anterior chamber of the eye via slit lamp. Antibody and antigen detection tests are less well developed than for LF.

In late stages, *Onchocerca* infection may produce “hanging groin” or scrotal elephantiasis as a result of recurrent lymphadenitis and loss of skin elasticity. Histology demonstrates atrophy and fibrosis of inguinal lymph nodes with subcutaneous edema and fibrosis. Onchocerciasis is also occasionally accompanied by massive inguinal lymphadenopathy.

Ivermectin is the treatment of choice (150 µg/kg orally once, repeated every 6 to 12 months until patient is asymptomatic), although it kills only microfilariae. Ivermectin must be used with caution if coinfection with *L. loa* is possible. Adverse effects include fever, rash, dizziness, pruritus, myalgias, arthralgias, and lymphadenopathy, mostly caused by dying filariae and *Wolbachia*. Six weeks of doxycycline (200 mg/day orally) kills more than 60% of adult female worms and sterilizes most of the remainder (Hoerauf, 2011). DEC should not be administered to persons infected with onchocerciasis because blindness and systemic toxicity can result from the resulting ocular and systemic inflammatory responses.

Loiasis is caused by *L. loa*, a filarial infection that is limited to Central and West Africa and transmitted by *Chrysops* flies. Adult worms migrate in subcutaneous tissues, and microfilariae circulate diurnally in the blood. *L. loa* does not harbor *Wolbachia*. Most infected persons have asymptomatic eosinophilia; some have urticaria, migratory subcutaneous lesions, and visible worms migrating across the conjunctivae (*eye worms*). Hematuria and proteinuria occur in 30% of patients; lymphadenitis and hydrocele also rarely occur. DEC (2 to 3 mg/kg orally three times a day for 14 to 21 days) is effective against loiasis, although multiple courses may be necessary (Klion and Nutman, 2011). Treatment can cause pruritus, arthralgias, migratory swellings, fever, eye worms, diarrhea, and renal failure. Patients with detectable microfilaremia (particularly more than 2500 to 8000 microfilariae per milliliter) are at risk of treatment-associated encephalopathy, which may be ameliorated by pretreatment apheresis. Albendazole (200 mg orally twice daily for 3 weeks) is associated with a lower risk of encephalopathy than DEC and may be safer in patients with high-grade parasitemia (Kappagoda et al, 2011).

Other Nonfilarial Genitourinary Parasites

Echinococcosis

Echinococcus granulosus is a cestode (tapeworm) that causes cystic echinococcosis. Infection results from ingestion of food or water contaminated with *Echinococcus* eggs or contact with infected dogs. Prevalence is high in pastoral communities, particularly in South America, the Mediterranean littoral, Eastern Europe, the Middle East, East Africa, Central Asia, China, Russia, and Australia. After infection the parasites encyst, usually in the liver or (less commonly) in the lungs. Although rare, cysts can grow ectopically in almost any organ in the body, with the kidneys being the third most common organ affected after the liver and lungs (<2% to 3% of cases) (Moscatelli et al, 2013). Initially, cysts are asymptomatic, but over time they enlarge (1 to 2 cm/yr) and eventually

cause pain or a palpable abdominal mass; hydatiduria and renal colic occur in a minority of patients. Renal function is usually unaffected. Imaging shows a thick-walled, fluid-filled spheric cyst, often with a calcified wall; the appearance helps define the stage of the disease and, in turn, management strategies. Serologic testing is adjunctive for diagnosis, with a sensitivity of only 60% to 90%. Although use of percutaneous puncture, aspiration, injection, and reaspiration (PAIR) is a good therapeutic option for liver cysts, this is not done for renal cysts, for which the only options are surgical resection or antiparasitic chemotherapy. Albendazole (400 mg orally twice per day for 1 to 6 months) is the recommended medical therapy (Kappagoda et al, 2011). Surgical excision is indicated in some patients because of the size or location of the lesions. Cyst rupture can cause anaphylaxis. Some evidence suggests that PZQ plus albendazole preoperatively and postoperatively may minimize secondary seeding and metastatic infection (Bygott and Chiodini, 2009).

Enterobiasis

Enterobius vermicularis (pinworm) causes enterobiasis, which occurs worldwide (common in both temperate and tropical countries). The worms live in the proximal colon and migrate to the perianal region to lay eggs, which become infectious after 6 hours. Transmission is mainly person to person, often via fecal-oral contamination of hands or fomites. Although most infections are asymptomatic, perianal pruritus can be severe. Rarely, pinworms can also migrate ectopically, including through the vagina, uterus, and fallopian tubes and into the peritoneal cavity of females. Dead worms and eggs incite granulomas and adhesions. Vulvar and cervical granulomas, salpingitis, oophoritis, tubo-ovarian abscess, appendicitis, and peritonitis can result. Epididymal involvement and inguinal hernias have been rarely reported in men (Moore and McCarthy, 2011).

Treatment with single-dose albendazole (400 mg orally) or mebendazole (100 mg orally) is highly effective. Alternatives include ivermectin (200 µg/kg orally once). Household and other close contacts should be treated, and treatment should be repeated after 2 weeks because of frequent reinfection and autoinfection (Kappagoda et al, 2011).

Amebiasis

Entamoeba histolytica, a protozoan transmitted by the fecal-oral route, is most common in tropical regions. Most infected persons remain asymptomatic, but 10% develop symptoms in other organs, including the kidneys. Cutaneous amebiasis can also occur, with painful ulcers often involving the perianal area and genitals (Peterson et al, 2011). Treatment is with tinidazole (2 g orally per day for 3 days) or metronidazole (750 mg orally three times a day for 10 days), followed by paromomycin (8 to 12 mg/kg orally three times a day for 7 days) or iodoquinol (650 mg orally three times a day for 20 days) (Kappagoda et al, 2011).

Trichomoniasis

Trichomonas vaginalis is a common sexually transmitted protozoan. See Chapter 15 for details.

Basic Immunology

Chronic Inflammation and the Endogenous Immune Response to
Genitourinary Cancers

Immunotherapy for Genitourinary Cancers

Cancer Vaccines

Immune Checkpoint Blockade in Genitourinary Cancers

Conclusions

Immunotherapy is emerging as an important treatment modality for multiple tumor types, including melanoma, lung cancer, and kidney cancer (Drake et al, 2014b). What is often forgotten as the field moves forward is the prominent role that immunotherapy has long played in bladder cancer (Brandau and Suttman, 2007). In fact, the use of bacille Calmette-Guérin (BCG) in bladder cancer provides an ideal framework through which to understand immunotherapy for genitourinary (GU) cancers, although there are still many unanswered questions regarding its mechanism of action. In addition to BCG, which is a relatively nonspecific agent, immunotherapy for GU cancer has also involved the concept of inducing a specific anticancer immune response via a cancer vaccine. Vaccine approaches for prostate cancer and kidney cancer will be discussed at some length; more detailed clinical information is included in specific chapters dedicated to treatment. Finally, recent clinical and laboratory data support a novel approach to immunotherapy: in many patients, it appears that antigen-specific immune responses to cancer are restrained by a specific set of molecules expressed on CD4 and CD8 tumor-infiltrating lymphocytes (TILs) (Pardoll, 2012). These “checkpoint” molecules are critically important in restraining an antitumor immune response, so treatment with monoclonal antibodies blocking specific checkpoint molecules such as CTLA-4 (cytotoxic T-lymphocyte antigen-4) and PD-1 (programmed death-1) can lead to objective clinical responses (i.e., tumor shrinkage) in approximately 30% of patients with kidney cancer. These checkpoint molecules will be introduced, and some early clinical data highlighted as well.

BASIC IMMUNOLOGY

The Innate Immune System

For didactic purposes, the immune system is often parsed into two basic divisions, the **innate** and the **adaptive**. Evolutionarily, the innate immune system is the older of the two, and it is present in all vertebrate organisms. Functionally, the innate system recognizes its targets through repeated patterns associated with pathogens. These pathogen-associated molecular patterns (PAMPs) are recognized by a series of receptors related to Toll molecules in *Drosophila*, and are known as *Toll-like receptors* (TLRs) (Medzhitov and Janeway, 2000). The binding of PAMPs to TLRs is a fundamental immunologic mechanism through which the organism recognizes “danger.”

Urologists who treat bladder cancer with intravesical BCG employ these innate immune immunologic mechanisms clinically; peptidoglycans in the BCG cell wall are canonical PAMPs, which bind to the Toll-like receptor TLR2 on innate immune cells resident in the bladder wall, serving to activate them and to initiate a cascading immune response (Brandau and Suttman, 2007).

The initial immune cell that responds to an invading pathogen (or to instilled BCG) is most likely a tissue-resident macrophage (Table 18-1). Their name is derived from the Greek *makros* (“large”) and *phagos* (“to eat”); macrophages are large cells that have evolved to engulf and destroy pathogens. Recognition of PAMPs by tissue-resident macrophages leads to their activation and subsequent secretion of chemical messengers known as *cytokines* and *chemokines* (see later), which in turn recruit and activate additional immune cells important in controlling a local infection. Again, BCG therapy for bladder cancer provides an excellent example, as both recognition by macrophages and the adherence of bacteria to urothelial cells lining the bladder results in the secretion of a series of chemokines and cytokines (Fig. 18-1). Some of these secreted cytokines attract a second cell type of major importance in the innate immune system, the neutrophil (also known as a *polymorphonuclear neutrophil* [PMN]). PMNs are the most abundant immune cell in the periphery and comprise approximately 60% of the white cells in the blood. These cells have a half-life measured in hours in the peripheral blood but can survive for days when present in the tissue at a site of infection or inflammation. In that sense, PMNs are the major cellular constituent of pus, and the hallmark of acute inflammation. One remarkable feature of neutrophil biology is their ability to emigrate from the circulation into tissues; this occurs when they squeeze between cells in the vascular endothelium as they follow a chemokine concentration gradient toward an area of infection within tissues. The hypersegmented configuration of their nucleus likely helps in this process by presenting a less formidable structural barrier to deformation. Like macrophages, neutrophils synthesize a variety of secretory granules that are released on PAMP recognition and that serve to facilitate destruction of an invading pathogen.

Cytokines and Chemokines

Cytokines and chemokines are small-molecule chemical messengers through which epithelial cells communicate with key cells in the immune system, and through which cells in the immune system

TABLE 18-1 Selected Cell Types Involved in the Immune Response to Genitourinary Cancers

CELL TYPE	IMMUNOLOGIC ROLE
Epithelial or urothelial cell	Secrete type I interferons as well as chemokines in response to stress, inflammation, viral infection, or danger signals mediated by pathogen-associated molecular patterns (PAMPs).
Macrophage	An innate immune cell that engulfs both pathogens and dead or dying cells. Secretes cytokines and chemokines to amplify or initiate an immune response.
Neutrophil (polymorphonuclear neutrophil (PMN))	The most numerous of all innate immune cells in the peripheral blood, critically important in controlling bacterial infections. A collection of neutrophils (pus) is a characteristic of acute inflammation.
Dendritic cell (DC)	The cell type that bridges the innate and adaptive immune systems by presenting antigens (peptides) from dead or dying cells or debris to T cells in the lymph node. Like macrophages, DCs are activated by “danger” signals transmitted through PAMPs, or by cytokines in the microenvironment.
CD4 T cell	A “helper” T cell; can help CD8 T cells to kill or B cells to secrete antibodies.
CD8 T cell	A “killer” T cell; once activated, serially lyses specific targets.
Regulatory T cell (Treg)	A subset of CD4 T cells characterized by expression of the transcription factor FoxP3. Major role is to downregulate an ongoing immune response. In cancer, this is generally a detrimental function.

communicate with one another. There are a large number of such molecules, and their nomenclature can be confusing. However, these molecules have a critical role in both acute and chronic inflammation, in the innate immune response, and in the adaptive immune response to cancer, so understanding a few key players is important. In this regard, the term *cytokine* is a rather general one, referring to any small immunologically relevant molecule secreted by a cell. Because many (but not all) of these molecules are involved in the migration of cells, the name derives from *cyto* (“cell”) and *kinesis* (“movement”). Typical cytokines include the type I interferons (IFN- α and IFN- β), which are produced by virally infected or otherwise stressed epithelial cells. Immunologically, type I IFNs render epithelial cells more sensitive to immunologic attack, by increasing their recognition by cells of the adaptive immune system, and also by directly facilitating epithelial cell death through a number of mechanisms. As discussed later, intravesical instillation of IFN- α has been evaluated in a number of clinical trials in bladder cancer, with encouraging but somewhat mixed results (Askeland et al, 2012).

The term *chemokine* refers to a subset of cytokines whose primary function is to induce the migration of immune cells along a

Figure 18-1. Activation of the innate immune system by bacille Calmette-Guérin (BCG). IL-8, interleukin-8; TNF- α , tumor necrosis factor- α . (Modified from Brandau S, Suttman H. Thirty years of BCG immunotherapy for non-muscle invasive bladder cancer: a success story with room for improvement. *Biomed Pharmacother* 2007;61:299–305.)

concentration gradient. The prototypic example is CXCL8, which can be secreted by most epithelial cell types, including bladder urothelium, in response to inflammatory signals. CXCL8 is a powerful chemoattractant for neutrophils and is likely important in the immune response to BCG in bladder cancer patients. The final subset of cytokines worth reviewing is a series of molecules originally described as facilitating communication between leukocytes, the interleukins. Interleukins were numbered in the order of their discovery, leading to an unfortunately complex situation in which an interleukin’s designation usually has very little to do with its functional role or cell of origin. Interleukin-1 (IL-1), for example, is really more of an innate cytokine than an interleukin; it is secreted from stressed epithelial cells, serves to attract a variety of immune cells, and in the systemic circulation is one of the primary mediators of an elevated temperature in response to infection. On the other hand, there are two discrete sets of cytokines associated with a broad polarization in the adaptive (T cell-mediated) immune response. These are termed the “Th1” and “Th2” family of cytokines (Tables 18-1 and 18-2; Fig. 18-2). These cytokines are secreted by CD4 (helper) T cells in response to various stimuli and are critically important in polarizing the immune system in one of several broad directions (Weaver et al, 2006). In bladder cancer, these patterns of response are especially important, because a Th1 response is associated with a successful response to BCG treatment whereas a Th2 response is associated with BCG failure (de Reijke et al, 1996; Thalmann et al, 2000; Saint et al, 2001, 2002). Mechanistically, this skewing occurs as naive CD4 helper cells are activated (see Fig. 18-2). In an environment rich in IL-12, they differentiate into Th1 CD4 T cells and in turn secrete IL-2, tumor necrosis factor- α (TNF- α), and IFN- γ . These Th1 cytokines, in turn, help to activate CD8 (killer) T cells and are important in a successful antitumor response. Conversely, when naive CD4 T cells recognize their targets in the context of IL-4, they differentiate into a phenotype associated with chronic inflammation and antibody production and in turn secrete IL-4, IL-5, IL-10, and IL-13. It is interesting to note that in bladder cancer these cytokines can be detected systemically after BCG treatment, so elevated serum IL-2 after treatment is associated with a favorable outcome. These are important data, showing that the immune effects of BCG are not merely local and illustrating the point that activation of the immune system in a single organ can have detectable effects throughout the entire organism.

TABLE 18-2 Selected Cytokines, Chemokines, and Interleukins Involved in the Immune Response to Genitourinary Cancers

CYTOKINE	CELL OF ORIGIN	ROLE
TYPE I INTERFERONS		
IFN- α	Urothelial cells Epithelial cells Macrophages	A type I interferon typically secreted by virally infected cells or cells sensing “danger” through Toll-like receptor (TLR) engagement. Upregulates class I MHC and antigen processing, rendering cells more susceptible to immunologic attack.
IFN- β	Urothelial cells Epithelial cells Macrophages	Similar to IFN- α , another type I interferon.
CHEMOKINES		
CXCL8	Urothelial cells Epithelial cells	A chemokine that is a powerful chemoattractant for neutrophils.
IL-1	Epithelial cells Macrophages	Like IL-8, also attracts other immune cells such as monocytes from the circulation.
SLC	Stromal cells in lymph nodes	Also known as CXCL21, SLC serves to attract activated dendritic cells and T cells into the lymph nodes. It is sensed by the receptor CCR-7.
INTERLEUKINS AND Th1 AND Th2 POLARIZATION		
IL-12	Dendritic cells	A Th1-inducing cytokine; when naive CD4 T cells are activated in the presence of IL-12, they differentiate into Th1 cells.
IL-4	Dendritic cells Natural killer T cells	A Th2 cytokine; when naive CD4 T cells are activated in the presence of IL-4, they differentiate into Th2 cells.
IL-2, TNF- α , IFN- γ	Th1 cells (CD4 T cells)	Canonical cytokines secreted by Th1 cells; associated with a favorable response to BCG in bladder cancer. These cytokines are also associated with inducing CD8 (killer) T-cell function.
IL-4, IL-5, IL-10, IL-13	Th2 cells (CD4 T cells)	Canonical cytokines secreted by Th2 cells; associated with an unfavorable response to BCG in bladder cancer. These cytokines are also associated with the induction of antibody production.

BCG, bacille Calmette-Guérin; IFN, interferon; IL, interleukin; MHC, major histocompatibility complex; SLC, secondary lymphoid chemokine; TNF, tumor necrosis factor.

The Adaptive Immune System

The adaptive immune system consists of CD4 (helper) T cells, CD8 (killer) T cells, and B cells. These cells are recruited into an immune response in response to activation of the innate immune system. They are important in two key facets of the immune response—its

specificity and its ability to “remember” antigen encounters and respond more robustly when an antigen is encountered again in the future. Before we expound on those properties, it is important to understand how information from the innate immune system is transferred to the adaptive immune system. This transfer depends on a unique cell type known as the *dendritic cell* (DC), which serves

as a bridge between an innate and an adaptive immune response. DCs get their name from their long and fine cytoplasmic projections, which microscopically resemble nerve cells. Functionally, DCs are scattered throughout the peripheral tissues, as exemplified by Langerhans cells in the skin. They spend the majority of their life span at rest, continually sampling their microenvironment, taking in fluid and protein antigens through the process of pinocytosis. In the absence of an activating or “danger” signal, DCs remain in situ and in a quiescent state. A danger signal can come in the form of cytokines such as $\text{TNF-}\alpha$ secreted from innate immune cells such as macrophages, or through direct contact with bacterial products through pattern receptors (TLRs) on DCs. When DCs are activated, a remarkable transition takes place. First, they cease taking in antigens, because their new role will be to present the antigens they have already taken up to T and B cells. Therefore their dendrites are retracted and the cells develop a more compact morphology. Second, they upregulate cell surface molecules important for presenting the antigens they are carrying to T cells. These include major histocompatibility complex molecules, which bind 9 to 12 amino acid peptide antigens in their grooves for interacting with specific receptors on T cells (TCRs), as well as a set of molecules designed to optimally stimulate T cells; these are called *costimulatory molecules* and include B7-1, B7-2, and others. Finally, DCs must solve a spatial problem: resting lymphocytes (T cells and B cells) reside in the secondary lymphoid structures—that is, in the lymph nodes—whereas resting DCs are situated in the tissues. Thus, DCs must migrate into the lymphatic system and enter into the lymph nodes through afferent lymphatic vessels. This is accomplished via chemotaxis; activated DCs follow a gradient of secondary lymphoid chemokine (SLC) using a receptor known as CCR7 into the lymph nodes. Once in the lymph nodes, DCs interact with (and activate) specific CD4, CD8, and B lymphocytes, facilitating the transfer of information from the innate to the adaptive immune system.

Thus, a CD4 T cell is activated when an antigen-presenting DC presents its cognate (specific) peptide antigen (usually 11 amino acids long) in the context of a class II major histocompatibility complex (MHC) molecule. These are helper cells; they either help CD8 T cells to become fully activated and exert their lytic function or assist B cells in making antibodies. As described earlier, CD4 T-cell responses fall into several basic categories, including a Th1 response, which serves to fully activate CD8 (killer cells), and a Th2 response, which serves to help B cells mature into antibody-secreting plasma cells. An additional CD4 T-cell subtype of interest is the

regulatory T cell (Treg). These cells suppress adaptive immune responses and appear to play a role in preventing a successful adaptive Th1- or CD8-driven anticancer response (Curiel, 2008). The origin of Tregs is complex; a population of “natural” Tregs arises de novo in the course of T-cell development in the thymus, and a second population is “induced” when naive CD4 T cells recognize their antigen in a microenvironment that is low in proinflammatory signals and rich in transforming growth factor- β (TGF- β) (see Fig. 18-2). The relative contribution of these two types of Tregs to the progression of GU cancers in humans is unclear; however, recent laboratory data point to a critical role for natural, thymus-derived Tregs (Savage et al, 2013).

Perhaps the most fascinating adaptive immune cell is the CD8 T cell. These cells recognize their specific cognate antigen 9 amino-acid long peptides in the context of class I MHC, which is present on almost all cell types but which is upregulated in the context of inflammation and on virally infected cells. When a specific CD8 T cell recognizes its target, it secretes a series of molecules that result in destruction of that cell type. This killing process is remarkably specific; in the autoimmune disease type 1 diabetes, CD8 T cells can lyse beta cells in the pancreas while leaving immediately adjacent alpha cells completely intact. The mechanism of killing is also exquisite; CD8 T cells employ multiple molecular mechanisms to induce their target cells to commit suicide—that is, to undergo programmed cell death or apoptosis. Finally, CD8 T cells are serial killers, able to lyse multiple specific targets in a sequential manner. As discussed later, the major goal of cancer vaccines is to activate antigen-specific CD8 T cells and to thereby eliminate an evolving tumor.

The Immune Editing Hypothesis

Before moving forward with a discussion of how the immune system may be manipulated to treat GU cancers, it is worthwhile to consider the immune system’s baseline role in either the promotion or the elimination of cancer. With the exception of certain virally mediated tumors that occur most commonly in immunocompromised individuals, most human cancers develop in immunologically intact hosts. As tumorigenesis proceeds from low-grade or localized disease to distant metastases, an interaction between the host immune system and the tumor mass occurs. This process has been well characterized in a number of animal models and can be divided into three distinct stages (Dunn et al, 2004) (Fig. 18-3). In

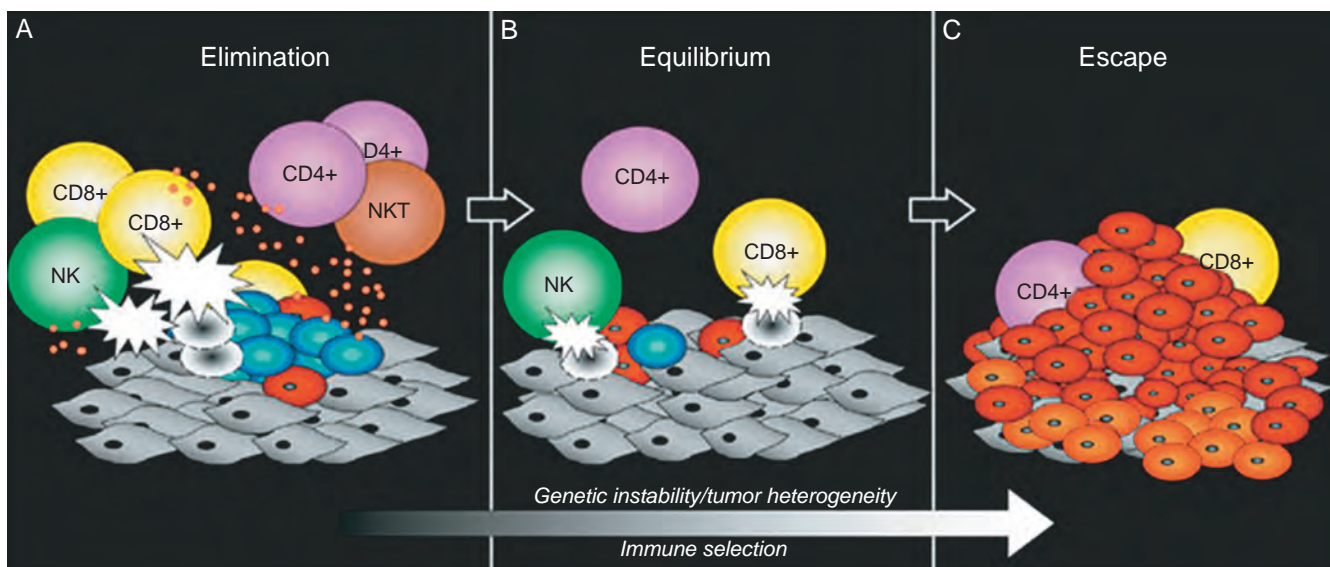

Figure 18-3. A–C, The immune editing hypothesis. NK, natural killer; NKT, natural killer T cell. (From Dunn GP, Old LJ, Schreiber RD. The immunobiology of cancer immunosurveillance and immunoediting. *Immunity* 2004;21:137–48.)

the first stage of the process, early tumors are recognized by the immune system in a productive, proactive way, leading to **elimination** of small, clinically undetectable masses. Elimination is most likely mediated by a concerted effort between the innate (macrophages and DCs) and the adaptive immune system. As tumors progress, they acquire genetic and epigenetic alterations that render an antitumor immune response less efficacious. Therefore in the next phase of tumor-immune system interactions, tumors are able to exist in a sort of **equilibrium** with the host immune response, with progression slowed by an ongoing immune response, but in which tumors can no longer be successfully eliminated. Equilibrium may persist for a significant period of time, and some tumors may remain in the equilibrium stage for the life of the host. Eventually, though, many tumors proceed to **escape** the host immune response and become clinically apparent. The molecular mechanisms involved in the escape phase are multiple and include downregulation of tumor antigens against which a host response is directed (Drake et al, 2006), downregulation of MHC molecules, and the induction or expansion of Tregs that actively inhibit an immune response. The three phases of tumor-host interactions (elimination, equilibrium, and escape) collectively form the immune editing hypothesis, which serves as a valuable framework through which to understand the immune response to cancer. Indeed, subversion of a productive host antitumor response is now designated as one of the hallmarks of cancer (Hanahan and Weinberg, 2011).

KEY POINTS: BASIC IMMUNOLOGY

- An immune response begins with an innate response that is swift but relatively nonspecific then progresses to include the adaptive immune system, which is characterized by both specificity and memory.
- For an antitumor immune response, a Th1 response dominated by IFN- γ , IL-2, and TNF- α is desired.
- CD4⁺ regulatory T cells (Tregs) inhibit an adaptive immune response.
- The immune editing hypothesis explains how early tumors can be recognized and eliminated by the immune system, whereas clinically evident tumors must escape immune recognition to evolve.

CHRONIC INFLAMMATION AND THE ENDOGENOUS IMMUNE RESPONSE TO GENITOURINARY CANCERS

Although the immune editing hypothesis would leave one with the impression that antitumor immune responses are, in general, beneficial, those data need to be considered along with a great deal of apparently contradictory data suggesting that inflammation can promote tumor progression (Balkwill et al, 2005; de Visser et al, 2006). Human and animal studies indicate that inflammation has a clear role in the development of bladder cancer (Michaud, 2007) and likely plays a role in the development of prostate cancer, as well (De Marzo et al, 2007).

Chronic Inflammation and the Immune Response to Bladder Cancer

Among the various GU malignancies, bladder cancer provides the strongest evidence for a link between chronic inflammation and carcinogenesis (Michaud, 2007). The evidence linking inflammatory schistosomiasis infections to bladder cancer is particularly robust, and *Schistosoma haematobium* has been classified as a known carcinogen by the International Agency for Research on Cancer. Epidemiologically, countries with high rates of endemic infection have high rates of bladder cancer, and high levels of infestation are

associated with a squamous cell phenotype (Mostafa et al, 1999). Other sources of bladder inflammation that have been linked to carcinogenesis include chronic urinary tract infections (Kantor et al, 1984), chronic indwelling catheters (Groah et al, 2002), and cystitis induced by cyclophosphamide treatment (Talar-Williams et al, 1996). The cellular and molecular mechanisms by which chronic bladder infection leads to cancer have not been fully elucidated but likely involve mechanisms similar to those described in other cancers (Mantovani et al, 2008)—that is, dysfunctional (M2) macrophages that produce immune suppressive cytokines, a subset of myeloid cells that suppress an active immune response (myeloid suppressor cells [MSCs]) (Ostrand-Rosenberg and Sinha, 2009), and a polarization of the adaptive immune response toward a Th2 and Treg phenotype.

Once bladder tumors develop, the immune editing hypothesis (see Fig. 18-3) would suggest that early tumors might be recognized by the immune system and eliminated. That hypothesis is supported by data showing that CD8 T-cell infiltration correlates with outcome in patients with muscle-invasive bladder cancer (Sharma et al, 2007). Obviously a successful CD8-mediated antitumor response does not occur in all patients, and recent data describe an important mechanism by which bladder tumors may “escape” immune recognition (Sharpe et al, 2007; Zou and Chen 2008; Pardoll, 2012). This occurs through the interaction between immune checkpoint molecules expressed on cancer-specific T cells and their checkpoint ligands, expressed on either tumor cells or tumor-associated macrophages (Fig. 18-4). This interaction is profoundly inhibitory to T-cell efficacy, attenuating proliferation as well as effector function. In this regard, several tissue-based studies showed that the epithelial cells in bladder cancer express the immune checkpoint ligand PD-L1 (Inman et al, 2007; Nakanishi et al, 2007; Xylinas et al, 2014). In the first of these studies, PD-L1 expression was noted in approximately 15% to 35% of patients, and expression was associated with increased tumor grade (Nakanishi et al, 2007). It is interesting to note that in these patients, PD-L1 expression was more closely associated with prognosis than was World Health Organization (WHO) grade, pointing to a functional role for PD-1/PD-L1 interaction in bladder cancer progression. A second, related, study confirmed the relationship between PD-L1 expression and high-grade tumors and further demonstrated that PD-L1 expression was associated with tumor infiltration by immune cells (Inman et al, 2007). This group also showed that PD-L1 was highly expressed in BCG-induced granulomas in patients progressing on therapy, suggesting a possible escape mechanism. Mechanistically, these data support a model known as “adaptive immune resistance” (Fig. 18-5), which explains how PD-L1 expression may be a critical mechanism by which tumors evade the immune response (Topalian et al, 2012a). In this model, mutations arising as a tumor progresses lead to an adaptive immune response, characterized by CD8 T-cell recognition. These CD8 T cells migrate to the tumor, and in the course of their effector function they secrete the cytokine IFN- γ . IFN- γ is a powerful inducer of PD-L1 expression in both tumor cells and epithelial cells, and it is these induced PD-L1 molecules on tumor cells that interact with PD-1 on the infiltrating CD8 T cells to effectively curtail their antitumor effector function. These data would suggest that a monoclonal antibody that blocks either PD-1 or PD-L1 could potentially lead to objective tumor responses in patients with bladder cancer—a hypothesis that is currently being tested in several ongoing phase 1 and phase 2 trials.

The Immune Microenvironment in Kidney Cancer

Unlike with bladder and prostate cancer, a link between chronic inflammation and kidney cancer is less clear and is only weakly suggested by the associations of kidney cancer with proinflammatory risk factors such as smoking or obesity (Chow et al, 2010). Regarding the adaptive immune response to kidney cancer, data are somewhat conflicting as to whether CD4 T-cell infiltration is a positive or negative prognostic feature in renal cell carcinoma (RCC) patients. One early study reported that CD4 T-cell infiltration is associated with an improved outcome (in the context of IFN- α

Figure 18-4. Immune checkpoint molecules. APC, antigen-presenting cell; MHC, major histocompatibility complex. (From Drake CG. Prostate cancer as a model for tumour immunotherapy. *Nat Rev Immunol* 2010;10:580–93.)

Figure 18-5. Adaptive immune resistance.

treatment) (Igarashi et al, 2002), but a more recent study suggested the opposite correlation (Hotta et al, 2011). Because neither study specifically examined whether the CD4 TILs were of the regulatory phenotype, differences in the number and/or function of CD4 Tregs could potentially explain that apparent contradiction. In this regard, as is the case in many other tumor types, tumor infiltration with Tregs has been described in RCC (Attig et al, 2009), and an association between both distant relapse and decreased overall survival with Treg infiltration has been reported in patients with clear cell RCC (Kang et al, 2013). Kidney tumors are also commonly infiltrated with CD8 T cells, suggesting an ongoing and potentially effective antitumor response, and the clonal nature of these infiltrating cells suggests an antigen-specific response (Sittig et al, 2013). As is the case for bladder cancer (Sharma et al, 2007), infiltration with proliferating CD8 T cells has been associated with an improved outcome in RCC (Nakano et al, 2001). Also similar to findings with bladder cancer, adaptive immune resistance is likely to play an important role in immune escape in kidney cancer, because PD-L1 expression has been associated with poor outcome (Thompson et al, 2007). Not unexpectedly, the CD8 T cells that infiltrate RCC express PD-1, suggesting that blocking PD-1 or PD-L1 in RCC could lead to clinical benefit. Several recent clinical trials support this concept, as is further described later.

Chronic Inflammation and the Immune Response to Prostate Cancer

Long before the appearance of clinical symptoms, the prostate microenvironment is frequently infiltrated by several types of

inflammatory cells including innate cells such as macrophages and adaptive cells such as T and B cells. This baseline inflammation is likely tumor promoting, and accumulating data from several groups support a model in which chronic prostatic inflammation drives the development of cancer (De Marzo et al, 2007). Multiple lines of evidence support this hypothesis. First, chronic inflammation in the prostate gland is frequently focused in the peripheral zone, the region in which more than 90% of tumors arise (McNeal et al, 1988). Second, epidemiologic studies show that Western nations, in which chronic prostatic inflammation is endemic, have a significantly increased incidence of prostate cancer as compared with Asian populations, in which inflammation is less prevalent (Sfanos and De Marzo, 2012). Finally, and perhaps most convincing, are data surrounding a prostatic lesion known as *prostatic inflammatory atrophy* (PIA) (De Marzo et al, 1999), a region characterized by flattened but proliferating epithelial cells and associated inflammatory cells. Morphologic studies showed that regions of PIA are located geographically proximal to high-grade prostatic intraepithelial neoplasia (PIN) lesions (Putzi and De Marzo, 2000), suggesting a possible etiologic link between PIA and the eventual development of cancer.

The adaptive T-cell environment of prostate cancer seems to be dominated by Tregs, which have been described both in the gland itself (Miller et al, 2006; Fox et al, 2007; Sfanos et al, 2008) and in the periphery (Yokokawa et al, 2008). A role for Tregs may extend even to metastatic lesions; recent studies by the Zhao group showed an increased prevalence of functional Tregs in the bone marrow of patients with prostate cancer (Zhao et al, 2012). In keeping with the notion of immunosuppression in prostate cancer, surprising data from both humans (Kiniwa et al, 2007) and animals

(Shafer-Weaver et al, 2009) suggest that in prostate cancer, CD8 T cells can also have a regulatory phenotype. In perhaps the most convincing of these studies, the McNeel group was able to show that regulatory CD8 T cells in the peripheral blood were sufficiently suppressive to mask an antigen-specific T-cell response driven by vaccination (Olson et al, 2012). Finally, as in other GU cancers, there is some evidence that the PD-1/PD-L1 axis may restrain an adaptive T-cell response to prostate cancer, because the CD8 T cells that infiltrate the prostate gland are clearly PD-1 positive (Sfanos et al, 2009). However, PD-1 blockade as a therapeutic maneuver for prostate cancer may be diminished by the finding that the tumor cells themselves do not appear to express PD-L1, suggesting either an intrinsic inability to upregulate the molecule or an absence of productive (IFN- γ) mediated inflammation. Taken together, these data suggest that prostate cancer develops in an environment characterized by chronic inflammation as well as a nonproductive adaptive CD4 and CD8 T-cell response (Bronte et al, 2005; Gannon et al, 2009).

KEY POINTS: CHRONIC INFLAMMATION AND THE ENDOGENOUS IMMUNE RESPONSE TO GENITOURINARY CANCERS

- Bladder cancer may be promoted by chronic inflammation initiated by infection or other stimuli.
- In kidney cancer, there is good evidence for an ongoing adaptive, T cell-mediated response, but that response is, in general, nonproductive.
- Prostate cancer may also be initiated through chronic inflammation.
- Expression of immune checkpoint molecules on TILs may attenuate the adaptive immune response to GU tumors.

IMMUNOTHERAPY FOR GENITOURINARY CANCERS

Bacille Calmette-Guérin in Bladder Cancer

The mechanism of action of BCG provides an excellent framework through which to understand the course of an induced immune response, an understanding that will be useful in appreciating the mechanisms of other immunotherapy modalities described later (Brandau and Suttman, 2007) (Fig. 18-6). The process begins with the instillation of 1 to 5×10^8 viable mycobacteria into the bladder. Most of these will be washed out with the first postinstillation void, but a significant fraction will adhere to the urothelial cells lining the bladder via a fibronectin attachment protein (Kavoussi et al, 1990). Repeated patterns (PAMPs) on the bacteria stimulate the urothelial cells to secrete cytokines, likely through the Toll-like receptors TLR-2 and TLR-4. Direct activation of resident macrophages and DCs by BCG components is also likely but has been less well described. The BCG-stimulated urothelial cells initiate a cascading immune response by secreting the chemokine IL-8 (among many others), and IL-8 is a powerful neutrophil attractant. TNF- α is also secreted, and in this setting this Th1 family cytokine recruits and activates macrophages. A few hours after BCG instillation, a wave of neutrophils migrates into bladder wall (de Boer et al, 1991). This wave of neutrophils is characteristic of acute inflammation, and neutrophils clear residual bacilli by secreting cytotoxic granules in addition to releasing a series of cytokines that help activate DC to potentiate the eventual involvement of the adaptive immune system. The next step in this inflammatory cascade occurs over several weeks as an adaptive immune response, primarily CD4 T cell driven, is recruited to the bladder. Although the precise mechanisms through which CD4 T cells are involved have not been well documented in bladder cancer, this most likely occurs in the same manner as it does in other immune responses: DCs are activated by neutrophil- and urothelial cell-derived cytokines (in addition to bacterial products) and traffic to the draining lymph nodes, where they present antigens to CD4 T cells to activate specific lymphocytes. The antigenic targets of CD4 T cells during BCG therapy for bladder cancer have not been well described but likely include bacterial

Figure 18-6. Bacille Calmette-Guérin (BCG) and an adaptive immune response. DC, dendritic cell; MHC, major histocompatibility complex; TCR, T-cell receptor; TLRs, Toll-like receptors. (Modified from Brandau S, Suttman H. Thirty years of BCG immunotherapy for non-muscle invasive bladder cancer: a success story with room for improvement. *Biomed Pharmacother* 2007;61:299–305; and Drake CG. Prostate cancer as a model for tumour immunotherapy. *Nat Rev Immunol* 2010;10:580–93.)

antigens as well as tissue- and tumor-specific antigens. Nevertheless, an adaptive immune response has been demonstrated to be required for successful BCG therapy of bladder cancer in laboratory studies (Ratliff et al, 1987), and the presence of CD4 T cell-rich granulomas in BCG-treated patients provides evidence that this may be the case in humans as well (Prescott et al, 1992). As mentioned earlier, the adaptive immune response is capable of generating long-lived memory T cells, which may persist for the life of a vaccinated patient. The generation of memory CD4 cells by BCG treatment of bladder cancer has not been well studied in patients, but their induction is strongly suggested by the significant fraction (approximately 50%) of patients whose non-muscle invasive disease remains in remission for years after BCG therapy. In summary, successful immunotherapy for bladder cancer represents a typical immune response, initially characterized by activation and involvement of the innate immune system (neutrophils and macrophages), which then transitions to an adaptive immune response driven by CD4 T cells polarized to secrete Th1 cytokines (IL-2, TNF- α , and IFN- γ), followed by eventual consolidation in the form of long-lived T-cell memory.

CANCER VACCINES

Like BCG, a “cancer vaccine” also aims to raise a T-cell response against cancer (Fig. 18-7). When a vaccine is injected into the skin, the components of the vaccine known as *pathogen-associated molecular patterns* (Medzhitov and Janeway, 2000) activate resting DCs and program them to migrate to a local lymph node. Thus, in general a vaccine includes some component(s) intended to activate DCs, although the precise substances employed vary among different vaccines. Another common term for these activating components is *adjuvant*, because they “add” immunogenicity to the protein or peptide components of a vaccine. The other key component of a vaccine is a target protein or proteins that are expected to be relatively overexpressed in a tumor relative to normal tissue. The choice of vaccine antigen(s) is somewhat empirical and, like adjuvant choice, varies widely among approaches. Once a resting DC has been loaded with antigen, has been activated, and has migrated to

a lymph node—it then displays fragments of antigen in the form of small peptides. Cellular recognition of these small peptide fragments (antigens) is complex; as introduced earlier, these peptides are not presented alone, but instead are bound within a genetically diverse set of host molecules collectively encoded by a set of genes within the MHC. Specific receptors on CD4 and CD8 T cells recognize a structure composed of both MHC molecules and a specific peptide. To increase specificity, simple recognition (a good fit) is insufficient for full T-cell activation; T cells must also receive additional costimulatory signals provided by mature DCs to proliferate and acquire effector function. In the case of CD8 T cells, the principal hoped-for effector function is the ability to lyse target cells expressing the same MHC-peptide complex that served to activate them—that is, their target antigen. For CD4 T cells, a Th1 response is desired. Once fully activated, CD8 T cells leave the lymph node and travel widely through the host in search of their targets. In the case of therapeutic cancer vaccines, the hoped-for goal is a clinically apparent reduction in tumor burden.

Vaccines for Kidney Cancer

Although an in-depth discussion of all the cancer vaccine approaches in GU cancers is beyond the scope of this chapter, several vaccines are highlighted. The chosen examples illustrate key immunologic principles, as well as the clinical challenges inherent in developing immunotherapy. In that regard, one interesting vaccine approach for kidney cancer focuses on targeting multiple, carefully selected antigens with a fairly simple adjuvant. To select relevant antigens, resected kidney tumors from a series of patients expressing the common class I MHC allele HLA-A2 were isolated, and the cell surface peptides residing in class I MHC molecules were eluted and analyzed with use of mass spectrometry (Walter et al, 2012). This approach identified a set of nine tumor-associated peptides, which were used to design a vaccine incorporating granulocyte-macrophage colony-stimulating factor (GM-CSF) as an adjuvant (Immunovax Biotechnologies, Tübingen, Germany). GM-CSF is a strong inducer of DC migration, but perhaps less robust than several of the TLR agonists in terms of inducing DC activation. In the phase 1 study of this agent (IMA901), 28 patients with RCC were enrolled; because

Figure 18-7. Cancer vaccines. DC, dendritic cell; MHC, major histocompatibility complex. (From Drake CG, Lipson EJ, Brahmer JR. Breathing new life into immunotherapy: review of melanoma, lung and kidney cancer. *Nat Rev Clin Oncol* 2014b;11:24-37.)

the peptides in the vaccine are presented only by the MHC class I allele HLA-A2, patients were required to be A2 positive. These patients received up to eight multi-peptide vaccinations, each preceded by GM-CSF as an adjuvant. The vaccine was well tolerated, with no grade 3 or 4 adverse events reported. At a 3-month follow-up point, a single patient showed a partial response, 16 patients had disease progression, and 11 had stable disease. Immune responses to the targeted peptides were detected in several of the treated patients (Walter et al, 2012). To improve the clinical activity of this kidney cancer vaccine, investigators made use of well-established data showing that low doses of the alkylating agent cyclophosphamide have vaccine-potentiating immune effects (North, 1982); these effects are at least partially mediated by the depletion of the Tregs that turn off an immune response (Machiels et al, 2001; Wada et al, 2009). In a randomized phase 2 trial, 68 HLA-A2–positive patients with RCC were randomly assigned either to vaccine or to vaccine preceded by a single immunomodulatory dose of intravenous cyclophosphamide (300 mg/m²). As noted in many other cancer vaccine trials, objective tumor regressions were rare, with a single confirmed partial response among 64 patients. Subsequent immunologic analyses showed an increased T-cell response to the targeted peptides and verified that low-dose cyclophosphamide depletes Tregs in humans. There was a trend toward improved overall survival in the vaccine plus low-dose cyclophosphamide arm (hazard ratio [HR] 0.57, *P* = .090), but this was not statistically significant. Despite these less than optimal phase 2 results, a randomized phase 3 trial was initiated in which IMA901 was added to a first-line tyrosine kinase inhibitor in patients with metastatic RCC (NCT01265901). Enrollment of 330 patients to this trial was completed in 2012. A second illustrative vaccine approach involves autologous vaccines, in which antigens are derived from a patient's individual tumor lysate or whole cells. Such vaccines have been tested in RCC and lung cancer (Simons et al, 1997; Eager and Nemunaitis, 2005), but autologous vaccine approaches are complicated by the variability and complexity in generating a vaccine from variable amounts of patient material. To overcome these challenges, a novel approach was developed, whereby a vaccine was generated using RNA extracted from patient-derived tumor material rather than tumor lysate or cells (AGS-003, Argos Therapeutics, Durham, NC). With this approach, substantial quantities of vaccine can be manufactured using a relatively small amount of resected tumor. Rather than relying on the patient's endogenous DCs (which are often defective or dysfunctional) (Gabrilovich et al, 1997), the AGS-003 vaccine uses autologous DCs generated ex vivo through maturation of immature monocytes in the presence of the cytokines IL-4 and GM-CSF (Palucka et al, 2005). To manufacture AGS-003, patients undergo leukapheresis, and DCs are cultured. Simultaneously, tumor RNA is prepared and used to transfect those autologous DCs to generate a mature, cell-based vaccine, which is then frozen and stored for repeated intranodal injections. In a phase 2 trial using the AGS-003 vaccine, the incorporation of sunitinib, a standard therapy for RCC, was shown to result in proimmunogenic properties (Figlin et al, 2012). A phase 3 trial of AGS-003 is currently in progress; this trial will randomly assign 600 patients with metastatic high-risk RCC to receive either ongoing treatment with the standard-of-care tyrosine kinase inhibitor sunitinib, or one cycle (6 weeks) of sunitinib followed by AGS-003 coadministered along with sunitinib (NCT01582672). The primary end point of the study is progression-free survival (PFS), and enrollment has not yet been completed. Taken together, these two vaccine approaches for kidney cancer illustrate some basic principles of cancer vaccines but highlight the notion that vaccination alone is unlikely to achieve objective clinical responses in the majority of patients treated.

Vaccines for Prostate Cancer

As highlighted earlier, an adaptive immune response depends on DCs, and a cancer vaccine, like any other vaccine, depends on the presence of a population of host DCs that are numerically and functionally competent. As noted previously, this is often not the case in cancer patients, in whom DCs are dysfunctional

(Gabrilovich, 2004). One approach to overcoming DC dysfunction is to generate new DCs outside of the patient's tolerogenic environment. In prostate cancer, this approach is exemplified by Sipuleucel-T, which was the first cancer vaccine approved by the U.S. Food and Drug Administration (FDA) for the treatment of patients with a solid tumor (Kantoff et al, 2010a). Sipuleucel-T is individually manufactured for each patient with prostate cancer in a process that includes multiple steps. Briefly, patients undergo leukapheresis; peripheral blood mononuclear cells (PBMCs) are extracted and then incubated with PAP2024, a fusion protein that links the antigen prostatic acid phosphatase (PAP) to GM-CSF. After approximately 36 hours of incubation, cells are washed and resuspended for infusion back into the patient. In this approach, the GM-CSF serves as the adjuvant that helps to activate DCs. The process is repeated three times at 2-week intervals (Sonpavde et al, 2012). Of interest, the final Sipuleucel-T product is heterogeneous and includes mature antigen-presenting cells (APCs) as well as other cell types, including T cells, B cells, and natural killer cells (Sonpavde et al, 2012). Once infused, the autologous ex vivo–activated APCs are thought to prime PAP-specific CD4+ and CD8+ T cells in a manner similar to a classical vaccine-mediated prime-boost regimen, in which the first infusion primes the immune system and subsequent infusions boost the response (Drake, 2010). Recently, a combined analysis of immunologic data from several phase 3 trials of Sipuleucel-T (D9901, D9902A, and IMPACT) was completed (Sheikh et al, 2013). These combined data demonstrated that APC activation in the infused product occurred with the initial dose and increased with subsequent doses. Furthermore, antigen-specific T-cell activity (proliferation) was detectable in preculture cells obtained at weeks 2 and 4 (but not week 0). Finally, T-cell activation–associated cytokines were also noted in the second and third doses of Sipuleucel-T, supporting the idea that the first infusion of activated, antigen-loaded APCs primes T cells in patients in vivo. These results also show that the second and third doses of Sipuleucel-T are biologically different from the first and that each dose contains progressively more activated APCs and possibly a greater proportion of antigen-specific T cells with the capacity to recognize and kill prostate cancer cells. Finally, the authors demonstrated a positive correlation between overall survival and cumulative APC activation and antigen-specific immune responses. Taken together, these analyses showed that Sipuleucel-T induces an antigen-specific immune response and that the response appears to be associated with a survival benefit in treated patients.

A second prostate cancer vaccine that has reached late stages of clinical development is ProstVac-VF (Bavarian Nordic, Washington, DC) (Madan et al, 2009). This vaccine approach is quite different from the peptide- or cell-based vaccines discussed previously and relies on the incorporation of a target antigen into a virus to specifically activate the immune system (Fig. 18-8). The antigen chosen for this approach is prostate-specific antigen (PSA), and the viral backbone comes from poxviruses, which are related to the vaccine used in the successful worldwide eradication of smallpox. This technology has been honed over several decades, and the iteration in a phase 3 trial includes a number of important modifications designed to optimize immunogenicity. First, the vaccine involves a heterologous prime-boost regimen, in which the initial vaccine is based on a modified vaccinia Ankara (MVA) backbone, followed by a series of booster vaccines with a fowlpox backbone. This is necessary because the immune response to the MVA backbone is quite robust, so boosting with an identical vaccine is limited by the host's immune antibody response to the viral backbone itself. To further increase immunogenicity, the vaccine was engineered to incorporate a triad of costimulatory molecules designed to generate DCs with an enhanced potential for T-cell activation (Hodge et al, 1999). Finally, and similar to IMA901 in RCC, administration of GM-CSF at the vaccination site is used to help recruit local DCs and enhance antigen presentation. In patients, poxvirus vectors most likely infect epithelial cells, a proportion of which undergo cell death. Cellular debris, including encoded antigens, are then taken up by nearby immature DCs, which, when appropriately activated, can present these antigens to CD4+ and CD8+ T cells in a

Figure 18-8. Virus-based cancer vaccines (ProstVac VF). APC, antigen-presenting cell; MHC, major histocompatibility complex; PSA, prostate-specific antigen; TCR, T-cell receptor. (From Drake CG. Prostate cancer as a model for tumour immunotherapy. *Nat Rev Immunol* 2010;10:580–93.)

proinflammatory context (Drake, 2010). Direct infection of DCs, particularly the Langerhans cells in the skin, is another mechanism by which poxvirus vectors can prime an immune response (Drake, 2010). The end result of ProstVac treatment is postulated to be activation and proliferation of PSA-specific CD8 and CD4 T cells, which was demonstrated in early correlative studies. In contrast to Sipuleucel-T (Sheikh et al, 2013), ProstVac-VF doesn't appear to prime much of an antibody response; indeed, antibodies specific for PSA have not been reported with this agent. Based on a potential survival benefit shown in a randomized phase 2 trial (Kantoff et al, 2010b), an international randomized phase 3 trial of ProstVac-VF was initiated (NCT01322490). This trial has enrolled 1200 patients and randomized them to placebo, ProstVac-VF plus subcutaneous GM-CSF, or ProstVac-VF alone. The primary end point of the trial is overall survival, and enrollment was limited to men with asymptomatic or minimally symptomatic metastatic castration-resistant prostate cancer (mCRPC) who are chemotherapy naive.

Genitourinary Tumors

GVAX Prostate (Aduro BioTech, Berkeley, CA) is a cell-based immunotherapy based on irradiated allogeneic tumor cell lines genetically engineered to secrete GM-CSF (Dranoff et al, 1993). The product uses two prostate carcinoma cell lines: the androgen-sensitive line LNCaP, as well as the castration-resistant line PC3 (Simons and Sacks, 2006). The immunologic concept underlying whole-cell vaccines such as this is that these cells may provide a source of multiple tumor- and tissue-specific antigens, at least some of which will correlate with those expressed in an individual patient's tumor. So, like IMA901 in kidney cancer, GVAX vaccines are considered polyvalent. However, unlike IMA901, the precise antigens recognized when a prostate cancer patient is treated with GVAX are not known. The theoretic advantage to polyvalent vaccines such as GVAX prostate (or AGS-003 in RCC) is that it is possible that the inclusion of multiple antigens might prevent tumors from escaping immune pressure by downregulating the expression of any one tumor-associated antigen. The major disadvantage of cell-based vaccines is that they are relatively difficult to monitor immunologically, because the key target antigens are not known for any particular patient. Mechanistically, GVAX prostate is thought to function in a manner similar to ProstVac-VF: irradiated cells are administered intradermally, where they undergo necrosis and are taken up by resident DCs attracted by secreted GM-CSF. After uptake of cellular debris and processing, antigens are presented to host

CD4 and CD8 T cells in draining lymph nodes in the context of host MHC molecules on the APCs. This process, called *cross-presentation*, has been demonstrated to occur in the clinic (Thomas et al, 2004). Although phase 2 trials failed to demonstrate clear clinical benefit, two randomized phase 3 trials were launched. The first of these was a 626-patient trial in which men with asymptomatic mCRPC were randomized 1:1 to GVAX Prostate or to chemotherapy with standard doses of docetaxel administered every 3 weeks (Higano et al, 2009). The primary end point of the trial was overall survival, but the trial was halted prematurely based on an unplanned and underpowered futility analysis. Thus, it remains unknown whether GVAX Prostate provides a survival advantage in men with early-stage mCRPC. A second trial, comparing the combination of GVAX Prostate and chemotherapy versus docetaxel chemotherapy alone was initiated, but enrollment was halted based on a reported imbalance in deaths, with an interim analysis showing 67 deaths in the GVAX plus chemotherapy arm, versus 47 in the chemotherapy-alone arm. The trial was permanently closed on the basis of that "imbalance," but follow-up data showed that, in a final analysis, there was no statistical imbalance in deaths, with 85 on the combination arm and 76 in the chemotherapy-alone arm. Taken together, the two GVAX trials support the safety of these cell-based vaccines in prostate cancer, but unfortunately no conclusions can be drawn about efficacy because both trials were halted before meeting prespecified enrollment criteria. An interesting facet of both trials is the choice of chemotherapy as a comparator arm; no large randomized clinical trial of immunotherapy in GU cancer either before or after this has chosen chemotherapy as a comparator, and these data, although clearly incomplete, suggest that comparing a cancer vaccine with chemotherapy is challenging.

IMMUNE CHECKPOINT BLOCKADE IN GENITOURINARY CANCERS

As discussed earlier, most tumors have evolved multiple mechanisms to evade immune-mediated destruction (Drake et al, 2006), and one of the most important of these mechanisms involves T-cell expression of one or more of a series of molecules that effectively limit T-cell proliferation and killing capacity (Chen 2004; Keir et al, 2008; Pardoll, 2012). Collectively these molecules are referred to as *immune checkpoints*; perhaps the best known of them is CTLA-4 (Hoos et al, 2010). Critically important preclinical studies using transplantable murine colon carcinoma and fibrosarcoma lines

showed that blocking CTLA-4 with a monoclonal antibody permits antitumor T cells to acquire effector function (Leach et al, 1996), a finding that has recently been borne out in randomized phase 3 studies in patients with metastatic melanoma. In two large, randomized phase 3 trials involving a total of 1178 patients, blocking CTLA-4 with the monoclonal antibody ipilimumab (Bristol-Myers Squibb, Princeton, NJ) resulted in a significant survival benefit. In the first of these studies, which enrolled previously treated patients, the median overall survival with single-agent ipilimumab was 10.1 months versus 6.4 months for patients treated with a peptide vaccine on the control arm (Hodi et al, 2010). In the second of these studies, which enrolled treatment-naïve patients and randomized them to either ipilimumab plus chemotherapy with dacarbazine or dacarbazine alone, median overall survival was 11.2 months versus 9.1 months. Long-term follow-up from the first trial showed that approximately 15% of treated patients were alive 5 years after enrollment. As reviewed elsewhere, CTLA-4 blockade is moving forward in lung cancer and other tumor types (Drake et al, 2014b). Because the immune checkpoint molecule CTLA-4 likely evolved to protect self-tissues from autoimmunity, it is not surprising that clinical trials of anti-CTLA-4 (including the pivotal phase 3 trials) were associated with an approximate 20% incidence of grade 3 and 4 immune-related adverse events (IRAEs), including colitis and dermatitis (Attia et al, 2005; Blansfield et al, 2005; Weber 2009; Lipson and Drake 2011). As introduced earlier, blocking a second immune checkpoint, PD-1, has also led to objective responses in melanoma, kidney cancer, and, perhaps somewhat surprisingly, lung cancer (Brahmer et al, 2010; Topalian et al, 2013). Toxicity rates for the two agents are difficult to compare because PD-1 blocking antibodies have only recently entered phase 3 development. Nonetheless, the rate of grade 3 and 4 adverse events does seem to be lower with PD-1 blockade than with CTLA-4 blockade (Topalian et al, 2012b, 2013), possibly because the PD-1/PD-L1 pathway acts more peripherally than the CTLA-4/B7-1 pathway, which likely operates in the lymph nodes (Ribas, 2012). In contrast to the cancer vaccines discussed earlier, objective tumor regression and long-term complete responses have occasionally been observed with either PD-1 or CTLA-4 blockade (Lipson et al, 2013). Although it remains unclear why cancer vaccines rarely generate objective tumor shrinkage, accumulating clinical data suggest that current vaccines are likely unable to effectively circumvent the multiple immunosuppressive mechanisms operative in the tumor microenvironment (Drake et al, 2006).

Bladder Cancer

Because bladder cancers frequently express PD-L1, blocking PD-1 and/or PD-L1 in that disease would seem a logical approach. Currently the PD-1 blocking antibody pembrolizumab (Merck, Whitehouse Station, NJ) and the PD-L1 blocking antibody MPDL-3280A (Genentech, South San Francisco, CA) are both in early-phase trials, but no mature data on response rates have yet been reported.

Kidney Cancer

In addition to multiple trials in melanoma, CTLA-4 blockade has also been tested in patients with metastatic RCC; a phase 2 trial conducted mostly at the National Cancer Institute (NCI) treated 61 patients with 3-mg/kg doses of ipilimumab every 3 weeks, or with a single 3-mg/kg loading dose followed by 1-mg/kg doses every 3 weeks. In this trial sequential cohorts were assessed, with no planned comparative analyses (Yang et al, 2007). Partial responses were observed in 5 out of 40 patients receiving the higher dose. As expected, grade 3 or 4 IRAEs were observed in 33% of patients; this appears to be a higher rate than that observed in melanoma patients, but likely reflects the continuous every-third-week administration regimen. It is interesting to note that a clear association between immune-related toxicity and responses was observed in this trial. At this time, single-agent CTLA-4 blockade is not under study in RCC, most likely because of competition from the plethora of targeted agents for kidney cancer, both FDA approved and in clinical trials.

Because RCC is usually considered to be an immune-sensitive tumor type, the observation of single-agent objective responses in RCC patients treated with single-agent anti-PD-1 in phase 1 trials was not completely unexpected. Indeed, a patient with advanced RCC showed a stable partial response for over 4 years in the first-in-human dose-escalation study (Brahmer et al, 2010). Perhaps more noteworthy, this sustained partial response eventually evolved into a documented complete response, and the patient had remained off treatment for longer than 5 years at last follow-up (Lipson et al, 2013). This initial indication of clinical activity for PD-1 blockade in RCC was supported by data from the more dose-intensive phase 1b trial discussed previously (Drake et al, 2013). Here, the objective response rate was 30% to 35%, with an additional 10% of patients showing stable disease. Based on the activity seen in phase 1 trials, several phase 1 and 2 studies of PD-1 blockade using nivolumab in RCC were initiated. One interesting trial was a dose-ranging study (NCT01354431); this trial enrolled a total of 150 patients, randomized into treatment cohorts at doses of 0.3 mg/kg, 2 mg/kg, and 10 mg/kg, treated every 3 weeks (in contrast to the once every-2-week administration in the phase 1b study). Accrual to that trial has been completed, but final data have not yet been reported. A second trial (NCT01358721) mirrors that design but incorporates pretreatment and post-treatment biopsies in an effort to discover predictive biomarkers for PD-1 blockade in RCC. Because treatment with the tyrosine kinase inhibitor sunitinib appears to confer antitumor immune modulating effects (Finke et al, 2008), a phase 1 study combining PD-1 blockade with either of the tyrosine kinase inhibitors pazopanib and sunitinib was initiated; that study is currently ongoing (NCT01472081). Most important from a clinical standpoint is a potentially pivotal, randomized phase 3 study (NCT01668784); that study, which has completed accrual, randomized 820 previously treated RCC patients in a 1:1 ratio to receive either nivolumab at a dose of 3 mg/kg every 2 weeks or to standard second-line therapy with the mammalian target of rapamycin (mTOR) inhibitor everolimus given at a dose of 10 mg once daily. The primary end point of the study is overall survival. Overall, the clinical experience with immune checkpoint blockade in RCC has been thus far favorable, with a measurable rate of objective responses and a tolerable toxicity profile. Still, without randomized phase 3 data the overall clinical impact of these agents has yet to be determined.

Prostate Cancer

As was the case for RCC, immune checkpoint blockade using anti-CTLA-4 (ipilimumab) was evaluated in a number of early-phase studies in men with prostate cancer. These data were recently summarized by Slovin and colleagues and show that treatment is associated with a PSA response rate of approximately 15% to 20%, but with few objective (radiographic) responses (Slovin et al, 2013). In several of these studies, a low dose of radiation therapy (RT) was tested in an effort to “release antigen” and potentiate an immune response. However, in the small dataset accumulated to date, there was no evidence for such an effect; for example, the PSA response rate in patients treated with a dose of 10 mg/kg of ipilimumab was 12% in the presence of RT versus 25% without. Despite this relatively low PSA response rate and little evidence that low-dose RT applied to a single lesion in men with metastatic disease improved the PSA response rate to ipilimumab, a phase 3 trial combining RT and ipilimumab was launched in men with mCRPC who had progressed on or after treatment with docetaxel chemotherapy. This trial enrolled approximately 800 men and randomized them to a single low-dose treatment of RT alone versus RT followed by ipilimumab at a dose of 10 mg/kg every 3 weeks \times 4, with every-3-month maintenance for men who were not progressing. The primary outcome of this trial was overall survival, and results were recently reported (Drake et al, 2014a). The trial did not meet its primary overall survival end point, with a median overall survival of 11.2 months in the ipilimumab group versus 10.0 months for placebo. The prespecified secondary end point of PFS was met, with a PFS of 4.0 months in the ipilimumab group versus 3.1 months in the

placebo group (HR = 0.070, $P < .001$). These data provide additional evidence that ipilimumab may have clinical activity in prostate cancer but are clearly insufficient for regulatory approval. Retrospective analyses of the phase 3 data showed that men with more favorable disease characteristics (no visceral metastases, normal alkaline phosphatase, normal hemoglobin) appeared to potentially benefit from treatment, although post hoc analyses of that sort require verification in a prospective trial. One fascinating finding in these post hoc analyses was that men with visceral benefit appeared to derive absolutely no benefit from ipilimumab treatment, whereas in men with bone-only disease there was a clear suggestion of clinical benefit. The precise mechanisms underlying this dichotomy are unclear, but it may reflect a different immune microenvironment in bone versus soft tissue metastases in prostate cancer. Relevant to those findings, a second phase 3 trial in the prechemotherapy setting has also completed enrollment; that trial specifically excluded men with soft tissue disease, perhaps boding well for its success. In summary, these data suggest that ipilimumab may have some activity in mCRPC, but the results of the second phase 3 trial will be required for that clinical question to be answered in a definitive manner.

PD-1 blockade has also been evaluated in a small number of patients with mCRPC, the majority of whom were heavily pretreated (Brahmer et al, 2010; Topalian et al, 2012b). These data were, in general, disappointing; no objective responses were noted in approximately 20 men. Biologically, the lack of response to PD-1 blockade in prostate cancer might be explained by the notion that prostate cancer cells do not appear to express PD-L1, although the majority of CD8 T cells that infiltrate the gland do express PD-1 (Sfanos et al, 2009). Taken together, immune checkpoint blockade will likely play an important role in treating RCC and possibly in bladder cancer—but additional combinatorial efforts will almost certainly be required for achievement of objective responses in men with later-stage prostate cancer.

KEY POINTS: IMMUNOTHERAPY FOR GENITOURINARY CANCERS

- BCG therapy for bladder cancer stimulates both the innate and adaptive immune systems and is a prototype for successful cancer immunotherapy.
- Cancer vaccines have been evaluated in both kidney and prostate cancer, and a single vaccine (Sipuleucel-T) is FDA approved for metastatic prostate cancer.
- Cancer vaccines are usually well tolerated but result in few objective clinical responses.
- Blocking immune checkpoints with monoclonal antibodies shows significant clinical promise in both kidney cancer and bladder cancer, but for unclear reasons appears to be less effective in prostate cancer.

CONCLUSIONS

Cancer immunotherapy is a rapidly advancing field of both clinical and preclinical study, and progress in this area has been especially strong in the case of GU cancers. A more robust understanding of both basic immunology and immune resistance to tumors has driven recent progress, and a large number of trials are ongoing.

One should not lose sight of the fact that BCG immunotherapy for bladder cancer was one of the first immune-based treatments to enter into routine clinical practice in any cancer type. As discussed in other chapters, the future of immunotherapy will most likely involve combination approaches, anchored in immune checkpoint blockade but weaving in RT, conventional chemotherapy, and perhaps initial immune activation via cancer vaccines.

Telomeres and Telomerase

Apoptosis

Stem Cells and Cancer

Despite decades of intensive biomedical research, cancer remains a significant cause of morbidity and mortality worldwide. This situation is due in part to the complexity inherent in this disease, which is not truly a single disease at all but well over 100 separate subtypes, all grouped together under the single term “cancer.”

In the United States alone, cancer strikes more than half a million people annually and is currently the second leading cause of death; if more recent trends continue, it is poised to become the leading cause of death in the near future. According to statistics reported in 2013, genitourinary (GU) malignancies comprise 29% ($n = 480,240$) of all cancer cases in the United States (nonmelanoma skin cancers excluded) and 15% ($n = 88,270$) of all cancer deaths (Siegel et al, 2013). However, significant advances have been made in the diagnosis and treatment of certain GU cancers. For example, the cure rate for testicular cancer now approaches 100% (Einhorn, 2002; Horwich et al, 2006). Testicular cancer is unusual in its responsiveness to therapy and is relatively uncommon. There has been less success with the more prevalent GU malignancies such as prostate, bladder, and renal cancers—the first (prostate), sixth (bladder), and eighth (renal) most common cancers (Siegel et al, 2013). However, mortality figures for these malignancies have shown a slow but steady decline over the past decade, and these trends are likely to continue and even to accelerate in the future.

Much of the current understanding of cancer is the direct result of the molecular biology revolution that developed rapidly following the elucidation of the molecular structure of DNA by Watson and Crick in 1953. In subsequent years, the field of molecular genetics has complemented and greatly expanded on knowledge gleaned by other disciplines, such as biochemistry and cell biology, providing important insights at the molecular level regarding the abnormalities present in cancer cells. More recent years have seen a tremendous expansion in the tools available for studying the genetic basis of human cancer, including whole genome and whole “exome” (the coding regions of the genome) sequencing efforts that have become relatively affordable and routine. A great deal is now known concerning the numerous molecular signaling pathways that provide both positive and negative regulatory signals, which in normal cells stringently control cell proliferation such that any losses in cell number are precisely counterbalanced, maintaining tissue and organ homeostasis—processes that go awry in cancer cells. Renegade populations of autonomously proliferating cells represent a serious threat to survival of the organism, particularly to large, long-lived species such as humans, and we have evolved multiple barriers to prevent such outbreaks from occurring. Incipient cancer cells must overcome several hurdles on the way to becoming fully malignant—a multistep process that takes many years to decades to complete. Cancer cells need to acquire at least

eight key attributes to make the transition from a normal cell to a malignant one, including (1) genetic instability and mutation, (2) autonomous growth, (3) insensitivity to internal and external antiproliferative signals, (4) resistance to apoptosis and other forms of induced cell suicide, (5) unlimited cell division potential, (6) the ability to induce new blood vessel formation (angiogenesis), (7) locally invasive behavior that uniquely distinguishes malignant from benign neoplasms, and (8) evasion of the immune system. In addition, cancer cells need to deal with various cellular stresses that are by-products of their abnormal physiology and increase their energy metabolism required to fuel autonomous growth and unlimited replication. Also, tumor-associated inflammation may drive the development of early preneoplastic lesions into invasive cancers and promote tumor progression. Finally, many cancers develop an additional, lethal attribute—the ability to leave the site of the primary tumor to colonize and thrive in distant organs or tissues as metastases (Hanahan and Weinberg, 2000; Solimini et al, 2007; Luo et al, 2009; Hanahan and Weinberg, 2011).

This chapter outlines fundamental concepts of molecular genetics that are directly related to human cancer in general, with an emphasis on GU malignancies in particular. Spurred by more recent technologic advances such as high-throughput DNA sequencing, knowledge of the molecular genetics of cancer is rapidly expanding, providing new insights that are just beginning to be successfully exploited for use in novel diagnostic, prognostic, and therapeutic applications.

TUMOR SUPPRESSOR GENES AND ONCOGENES

For a detailed description of basic molecular genetics (DNA, RNA and transcription, protein synthesis, chromosomes, and gene structure) see the Expert Consult website.
